CONTENTS OF VOLUME 118

JULY, 1961

PRESIDENTIAL ADDRESS. <i>Robert H. Felix</i>	1	Long-Term Results of Frontal Lobotomy in Schizophrenic Patients. <i>Jane E. Olman, and Samuel Friedman</i>	70
ROBERT HANNA FELIX. <i>Francis J. Braceland</i>	9	An Evaluation of Aescin (An Extract of Horse Chestnuts) in the Treatment of the Psychoses of the Senium. <i>Kenneth Lifshitz, and Nathan S. Kline</i>	72
CULTURE AND MENTAL ILLNESS. <i>Ashley Montagu</i>	15	Drug-Induced Hepatic Injury: Marplan Hepatitis. <i>James A. Knight</i>	73
A VISIT TO THE ARGENTINE. <i>Joseph Worriss</i>	24	Experiences with Elavil: Treatment of Fifty-One Cases of Depression. <i>Maurie D. Pressman, and Lawrence B. Weiss</i>	74
THE TREATMENT PROGNOSIS FOR FUNCTIONAL PSYCHOSES IN GREAT BRITAIN. <i>William Sargant</i>	29	Serum Transaminase for Liver Function on Outpatients in Follow-Up Clinic. <i>Yudell K. Slocum</i>	75
MENTAL DISEASE OR DEFECT EXCLUDING RESPONSIBILITY. <i>Lawrence Z. Freedman, Manfred Guttmacher, and Winfred Overholser</i>	32	Imipramine (Tofranil) in the Treatment of Enuresis. <i>Anna J. Munster, Alfred M. Stanley, and John C. Saunders</i>	76
THE PROGNOSIS IN UNPSYCHOANALYSED RECOVERY FROM NEUROSIS. <i>Joseph Wolpe</i>	35	Diabetic Control with Chlorpropamide in a Psychiatric Hospital. <i>Thomas G. Lupo, and Stanley M. Tarnowski</i>	77
DIFFERENTIAL ASSESSMENT OF POSTHOSPITAL PSYCHOLOGICAL FUNCTIONINGS: EVALUATIONS BY PSYCHIATRISTS AND RELATIVES. <i>Benjamin Pasamanick, and Leonard Ristine</i>	40	CASE REPORTS:	
RELAXANT ANAESTHESIA FOR ELECTROPLEXY. <i>S. V. Marshall</i>	47	Effect of Imipramine (Tofranil) on Depression and Hyperkinesia in Huntington's Disease. <i>J. Whittier, G. Haydu, and J. Crawford</i>	79
MONISM AND DUALISM IN THE STUDY OF BEHAVIOR. <i>Max Levin</i>	53	Report of a Case of Carcinoma of the Lung with Metastasis to the Brain, Simulating Pick's Disease. <i>James K. Hall, Jr.</i>	80
DIFFERENTIATING VARIABLES: OBSESSIVE-COMPULSIVE NEUROSIS AND ANOREXIA NERVOSA. <i>John Clancy, and Albert Norris</i>	58	COMMENTS:	
PROCESS, SCHIZOPHRENIC AND THERAPEUTIC: SOME MISCONCEPTIONS RESULTING FROM LANGUAGE AND PHILOSOPHY. <i>Edward S. Dean</i>	61	Chicago Meeting Highlights	82
CLINICAL NOTES:		When is a Doctor Not a Doctor?	84
Increased Control of Insulin Coma by Prior Administration of Glucagon. <i>Karl T. Dusik, Donald B. Giddon, Peter D. Watson, and Joel J. White</i>	66	The Editorial Board	84
Effects of Chlordiazepoxide in Severely Disturbed Outpatients. <i>Felix Bambace</i>	69	CORRESPONDENCE:	
		Treatment of Cardiac Arrest	85
		NEWS AND NOTES	86
		BOOK REVIEWS	88
		IN MEMORIAM:	
		Arthur H. Ruggles	93
		William Noble Keller	94

AUGUST, 1961

THE AETIOLOGY AND TREATMENT OF CHILDREN'S PHOBIAS: A REVIEW. <i>S. Rachman, and C. G. Costello</i>	97	PATIENT FREEDOM: A VIEW FROM MICHIGAN. <i>Iver F. Small</i>	139
A RE-EXAMINATION OF THE PHOBIC SYMPTOM AND OF SYMBOLISM IN PSYCHOPATHOLOGY. <i>Silvano Arieti</i>	106	PSYCHIATRIC DISORDERS AND MYXEDEMA. <i>Ferris N. Pitts, Jr., and Samuel B. Guze</i>	142
THE CHAIN OF CHRONICITY. <i>Robert Sommer, and Gwyneth Witney</i>	111	NURSING WARD THERAPY AS AN ALTERNATIVE FOR RESTRAINT. <i>Karel Planansky, and Roy Johnston</i>	148
ECOLOGICAL FACTORS IN HUMAN MALADAPTATION. <i>James K. Feibleman</i>	118	TRANLYCYPROMINE (PARNATE) IN THE AMBULATORY TREATMENT OF DEPRESSED PATIENTS. <i>Max L. Lurie, and Harry M. Salzer</i>	152
THE MEASUREMENT OF AN INHIBITORY PROCESS IN HUMAN HIGHER NERVOUS ACTIVITY. <i>N. McConaghy</i>	125	RESULTS OF SIMULTANEOUS ABRUPT WITHDRAWAL OF ATARAXICS IN 500 CHRONIC PSYCHOTIC PATIENTS. <i>L. N. Judah, M. Josephs, and O. D. Murphree</i>	156
SPIRIT POSSESSION IN HAITI. <i>Arnold</i>	133		

CLINICAL NOTES :

The Effect of Amphenidone (Dornwal) in Anxiety States : A Multi-Blind Study. <i>H. Azima, Dorothy Arthurs, and A. Silver</i>	159
A Clinical Evaluation of Four Antidepressant Drugs. <i>Paul C. Agnew, Irving D. Baran, Howard J. Klapman, P. Theodore Reid, Jr., Jerry J. Stern, and Roger H. Slutske</i> ..	160
CASE REPORTS :	
The Phobic Anxiety-Depersonalization Syndrome. <i>I. Pierce James</i>	163
Electroconvulsive Therapy Following an Operation for Coarctation of the Aorta. <i>Shirley Rubert</i>	165
Six Months Observation of Psychotic Identical Twins. <i>David W. Swanson</i>	166
Severe Papilledema Associated with Drug Therapy. <i>Arnold G. Blumberg, and Donald F. Klein</i>	168

Extreme Eosinophilia During Imipramine Therapy. <i>R. J. Joynt, and J. Clancy</i>	170
Loss of Ejaculation During Mellaril Treatment. <i>Fritz A. Freyhan</i>	171
Inhibition of Ejaculation as a Side-Effect of Mellaril. <i>Michael Green</i>	172
Another Case of Inhibition of Ejaculation as a Side-Effect of Mellaril. <i>Joseph Heller</i> ..	173
HISTORICAL NOTES :	
Benjamin Rush's Son. <i>Franklin S. Klaf</i>	174
Psychotherapy by Reciprocal Inhibition. <i>Mark A. Stewart</i>	175
COMMENTS :	
Soviet Psychiatric Nomenclature	178
OFFICIAL REPORT :	
Report of the Chairman of the Board of Tellers	181

OCTOBER, 1961

PSYCHIATRY AND LAW: USE AND ABUSE OF PSYCHIATRY IN A MURDER CASE. <i>Fredrick Wiseman</i>	289	Drug in the Phenothiazine-Induced Extrapyramidal Reaction. <i>William Mandel, and W. A. Oliver</i>	350
REVIEW OF RAPID URINE TESTS FOR PHENOTHIAZINE AND RELATED DRUGS. <i>Fred M. Forrest, Irene S. Forrest, and Aaron S. Mason</i>	300	Recurrent Thioperazine-Induced Extrapyramidal Reaction Following Placebo Substitution for Maintenance Antiparkinson Drug. <i>William Mandel, Bessie Claffey, and Lester H. Margolis</i>	351
THE CURRENT STATUS OF PSYCHIATRY IN THE UNITED KINGDOM. <i>Henry P. Laughlin</i>	308	Tranlycypromine and Trifluoperazine in the Treatment of Dangerous Hospitalized Patients. <i>Anthony Lapolla</i>	352
THE RESPONSE OF SEVERELY ILL CHRONIC SCHIZOPHRENIC PATIENTS TO SOCIAL STIMULATION. <i>J. K. Wing, and R. K. Freudenberg</i>	311	Behavioral Evaluation of Imipramine and Nialamide in Regressed Schizophrenic Patients with Depressive Features. <i>Carl A. Leuthold, F. J. Bradshaw, G. W. Arndt, E. F. Hoffman, and Vladimir Pishkin</i>	354
A COMPARISON OF PROMAZINE AND PARALDEHYDE IN 175 CASES OF ALCOHOL WITHDRAWAL. <i>William T. Hart</i>	323	Comparison of EST and Antidepressant Drugs in Affective Disorders. <i>Jane E. Olman, and Samuel Friedman</i>	355
THE PUERTO RICAN SYNDROME. <i>Captain Robert D. Mehlman</i>	328	Acetophenazine (Tindal) and Thiopropazate (Dartal) in Ambulatory Psychoneurotic Patients. <i>Harry F. Darling</i>	358
PSYCHIATRIC SYNDROMES, ANXIETY SYMPTOMS AND RESPONSES TO STRESS IN MEDICAL STUDENTS. <i>Ferris N. Pitts, Jr., George Winokur, and Mark A. Stewart</i>	333	CASE REPORTS:	
THE PSYCHIATRIC PATIENT AS HIS OWN HISTORIAN. <i>James A. Kenny, and Ronald C. Bounows</i>	341	Severe Hypertension with Parnate. <i>Mariano F. Songco</i>	360
CLINICAL NOTES:		Withdrawal Symptoms Following Ethchlorvynol (Placidyl) Dependence. <i>Heber S. Hudson, and Herbert I. Walker</i>	361
A "Double Blind" Study Comparing RO 4-0403, Trifluoperazine and a Placebo in Chronically Ill Mental Patients. <i>Antiocho Barron, Barbara Beckering, Lester H. Rudy, and Jackson A. Smith</i>	347	THE PRESIDENT'S PAGE	362
Clinical Observations of Therapeutic Effect of Chlorprothixene (Taractan) in Psychoses. <i>Leon Reznikoff</i>	348	COMMENTS:	
Withdrawal of Maintenance Antiparkinson		Third World Congress of Psychiatry	364

PRESIDENTIAL ADDRESS

PSYCHIATRIST, MEDICINAE DOCTOR¹

ROBERT H. FELIX, M.D.

This week will draw to a close my efforts to serve you as the eighty-ninth President of our Association. Needless to say, one approaches the end of such an exciting professional experience with mixed feelings. I venture that every President, however hard he has tried to render the best that is in him during his fleeting year, is virtually always bound to conclude that his best was not enough. At the same time, the experience engenders in him a new affection for his fellow psychiatrists who have so honored him and he will resolve anew to continue to serve them with redoubled efforts in other capacities. I am no exception to these phenomena.

There is about our Association, or so it seems to me, a special quality of commitment to the simple proposition that psychiatry can do something for the welfare of mankind. As President I have sensed this anew in working with members of our staff whose diligence I venture can only be explained in terms of their own sense of purposefulness in helping us to achieve our goals. My ear picks up the vital theme of purpose in the scores of committee deliberations in which a President participates. One detects it in the policy statements that the Association issues from time to time in the public interest. Its spirit is implicit in our avoidance, as an Association, of positions that would preserve ancient tradition and privilege in the face of changing social needs. It is evident in our openness and lack of defensiveness in our relations with the public and in our willingness over the long view to let our collective record speak in rectification of the incidental embarrassment. In a word, our Association is an instrument for the implementation of the

dedication that is in us. Its good works are on the record for all to see. Its potential for greater things to come is there for us to make the most of.

Later this week the mantle of my office will fall on the capable shoulders of Dr. Walter Barton. All of you, I am certain, share my own deep sense of comfort that our affairs will be guided by so able and devoted a physician and servant of psychiatry in the coming year. As for me, let me say as prelude to my parting words in this Address, that if I were proud to be a psychiatrist before you so honored me, my pride in being one of you has multiplied this past year. To all of you let me extend my humble thanks and with it my resolution to serve you as you have need of me with all the energy I can muster in years to come.

It is obvious, even to the casual observer, that there have been great advances in our field in recent years. No longer can we plead abysmal lack of knowledge or attribute the load of chronic patients in our hospitals to our great dearth of effective techniques for their management and treatment. Our knowledge has vastly expanded, even though we cry out for more and push impatiently and ever more vigorously at the frontiers to open up new vistas and add to our understanding of the many and varied phenomena which contribute to mental illness and to mental health. None of us here would say that we know more than a small fraction of what we must know—the uncharted areas are much larger than those we have even sketchily mapped. Now in this 7th decade of the 20th century, and the 117th year of our Association, we look both with hope and expectation to the not too distant future when scientists of many disciplines and skills will supply the answers we need—when out of dissonance will come harmony, out of confusion will come order, and that which is dark shall be illuminated.

¹ Presidential Address delivered at the 117th Annual Meeting, American Psychiatric Association, Chicago, Ill., May 8-12, 1961.

The findings to date and the hypotheses they have made possible are breath-taking ; and if, on testing, even a portion of these result in well defined theory, our world of psychiatry will look like nothing our colleagues of earlier generations would have dreamed possible. Moreover, even those hypotheses which cannot themselves be validated may and frequently do lead to new hypotheses based on the very data which were their undoing.

Many of these discoveries will not only be exciting and challenging but undoubtedly will rudely shake some of our presently held and cherished concepts. Such an experience is, at the least, disturbing, but it should not be devastating. Many of these concepts were brilliant deductions arrived at as a result of searching observation. They are the best we have and we find that they serve us. None of us would say that they are immutable truths nor the final answer. Many of them are quite probably pieces of a greater whole which will become manifest to us when more of the components have been assembled. With each new verified discovery we approach a little closer to the whole truth, and this, in the final analysis, is what we all seek. For truth is the ultimate reality, the *vera lux*.

It is, moreover, auspicious that our field is becoming attractive to workers in disciplines who formerly felt they could find no foothold or challenge in problems concerning the cause and treatment of the mentally ill. With the new information that has been acquired in the past few years, they now find their skills and techniques can be applied to solving the unanswered questions, and they are devoting themselves in increasing numbers to research on problems never before attacked from these points of view. Thus we see chemists studying the nucleic acids in relation not only to nervous system function as usually conceived, but also in relation to such psychological mechanisms as memory. The possible role of transmethylation in mental health and disease is beginning to be examined. The possible role of epinephrine and norepinephrine and their metabolism in mental health and mental illness has provided insights and opened new avenues to investigation. The interesting and highly specialized dispersal of the biogenic

amines within the nervous system, the action of drugs upon them, and their correlation with behavior is a large and exciting field only recently opened up. Physiologists are adding to our knowledge of the function of the limbic system and its significance in thought and behavior, both normal and pathological. The revolutionary concept of the graded response of the neuron, and the findings regarding the transmission of the nerve impulse across the synaptic junction are inevitably modifying and amplifying our understanding of some of the physiological bases of human behavior. The important field of psychopharmacology, that borderland between chemistry, physiology and psychology, is yielding up secrets which are promptly being applied to the treatment of the mentally ill with dramatic results both upon the patients themselves and upon the therapeutic milieu, including the attitudes of the treatment personnel. The social and other behavioral sciences are being vigorously explored and much of the findings of these scientists are of critical importance in the understanding of our patients.

The theoretic constructs which underpin psychodynamic theory are undergoing critical re-examination by a variety of disciplines to the end that its contributions to psychiatric principles and treatment techniques will rest on more sound foundations. Due to the rapidly improving state of our knowledge in all areas, we are becoming better positioned to develop further our field of medicine for meeting the tremendous demands being made upon us. So much for a few of the areas of investigation which are contributing new insights to understanding the mental illnesses. Already we can see heartening and positive results. Each year, for the past 5 years the mental hospital population in the United States has declined, reversing a trend of over a century's duration. Between 1955 and 1960, resident patients in our hospitals decreased by 4.2%, or over 28,000, from a high of 560,000. Even more dramatic is what has happened to our patient population projections. Projecting the trend for the 11 years 1944 through 1955, the expected patient load for 1960 was over 622,000. The actual figure of 535,332 patients is nearly 86,000 or 14% below the expected figure. This drop occurred despite an

average annual increase in admissions of over 6%, due to the fact that separations from the hospitals have exceeded admissions because of a steady increase of about 10% per year in the number of net releases.

The dramatic changes in our hospital population as described by these gross figures tell only part of the story, of course. There is occurring a change in the type of patients in our hospitals, and, because of this, a change in the types of patients seen in extramural settings, both public and private. Many of the chronic patients traditionally seen in our institutions are disappearing. With the new therapies both psychological and pharmacological, and with the innovations in hospital ward administration, there is more likelihood of effecting early and favorable change in the clinical condition of the patients under our care. The result has been more releases and an increasing emphasis on extramural care and on the importance of the community as a therapeutic resource. Accompanying this has been growing recognition of the less favorable influence of the large hospital as contrasted with the smaller one, and the therapeutic advantages of the hospital of 1000 beds or less.

General public acceptance of this philosophy—and it cannot come too soon for the good of the mentally ill—will be tantamount to a national decision to eliminate so far as we can the prolonged hospitalization and institutionalization of the mentally ill. Communities will do what they long since should have done, namely, provide the facilities and services that will forestall hospitalization whenever possible and give the convalescent mentally ill every chance to achieve maximum psychological and social recovery.

This will mean, among other things, that the elderly will not be hospitalized unless they are in fact mentally ill and actually need the kind of treatment that the psychiatric hospital can best provide. We are now well aware that the elderly may develop the same psychiatric disorders as those who are younger, and that they often respond as satisfactorily to treatment. Those who are suffering from depressions, neuroses or other illnesses are as entitled to energetic and intensive therapy as are those who are younger; and this therapy can and should

be administered outside of an institution, wherever possible.

These developments in psychiatry will inevitably lead to broadening and diversifying our activities whether we practice in private office, clinic or hospital. We have much more knowledge to put to use and a great deal more will be at our disposal in the future. This enhanced armamentarium and these responsibilities will require of each of us not merely a broad scientific and medical background, but also current knowledge concerning many aspects of medicine which will become more and more essential for the proper management of clinical problems. This means that not now or ever can we allow our medical skills to atrophy, if we are to keep abreast of our field as it develops and thereby give our patients that to which they are entitled—the best that can be obtained.

All of this is to say that a psychiatrist must be a good physician first and always, and that one cannot be a good psychiatrist however profound his knowledge of psychodynamics or however great his mastery of psychotherapy, unless this prerequisite is first satisfied. Being a good physician implies more than knowing and being able to apply a variety of technical procedures. It means first of all an attitude toward the sick, and one's patients in particular, which amounts to a total commitment to one's calling and to those under one's care. It means continual study and professional improvement to the end that patients can be better served. It means retaining and using a variety of basic medical skills which any patient has a right to expect of any physician regardless of his specialty. To restrict medical thinking and awareness exclusively to one special field is to become a technician, and a physician is much more than a technician.

An examination of the concept of psychiatry and psychiatrists held by both our medical colleagues and the public at large is very revealing, and gives helpful clues to understanding some of the attitudes toward us.

Psychiatry is defined as "the medical specialty that deals with mental disorders" (1); as "a special branch of medical science dealing with causes, symptoms, course and

treatment of disorders and diseases of the mind"(2); and as "the science which deals with the psychopathological aspects of human biology"(3).

The psychiatrist, we learn, must be a physician, a doctor of medicine licensed, or qualified to be licensed, to practice the healing arts who possesses special skills in the area of mental and emotional diseases and disorders. With this formulation all of us would agree. But what does it imply? Quite simply that the psychiatrist, being a physician, is required to possess and maintain competence in those skills which any physician must have, regardless of how general or restricted the physician's field of practice may be.

But what is a physician? What does the public think he is; and what is expected of him? He is described as "a person skilled in physic of the art of healing. One duly authorized to treat disease . . . ; a doctor of medicine . . ."(1).

This, then, is what we are. Practitioners of medicine, qualified as possessing the knowledge and skill to treat the sick. A recent inspection of my own license revealed that I am authorized to practice medicine and surgery in my state. The license of each of us either so states explicitly or such authority is implicit in the wording. And this is as it should be. It is a concept all of us were taught and all of us accept in principle. W. A. White(4), in his Presidential Address, in 1925, said, "Psychiatry . . . demands for its background the whole of medicine, because . . . it deals with the whole individual. . . . So the psychiatrist is a specialist in the reactions of the organism as a whole, and those reactions he cannot understand unless he knows all parts of the organism. . . . His principal medical qualification should be a broad, comprehensive, sympathetic contact with the whole field of medicine." Alan Gregg(5) addressed himself to this same concept at our Centennial Meeting in 1944. It was his opinion that a concern and current knowledge of medicine generally was essential not only for the best treatment of our patients, but also in order to "encourage observation and experiment instead of speculation."

Earlier, I said that to be a good physician one must possess more than skill in

diagnosis and treatment. One must also have developed an attitude of dedication to his calling and to those he serves. The good physician must have honor and integrity and a genuine respect and regard for his patient. He must have a deep conviction concerning the dignity of the individual and the inalienable right of every one to health. From this will have come a selfless devotion to duty and a well developed sense of public responsibility. He must be the dependable resource, the trustworthy friend, the wise counsellor, the good, discrete and skillful servant of man.

All of these attributes of character the physician must have in full measure, but in addition, there is certain technical knowledge he must also possess without regard to his type or degree of specialization.

It goes without saying, of course, that every physician can be expected to carry out a dependable general physical examination. I would go so far as to say that the physician who does not employ his stethoscope, his sphygmomanometer, his ophthalmoscope, and his percussion hammer regularly, should seriously question his capacity to make adequate diagnoses. Any physician in practice should be able to interpret the usually encountered heart and breath sounds; to identify a mass in the abdomen or breast; accurately to locate the liver margin; to diagnose a choked disc or silver wire deformity of retinal vessels; to identify tracheal tug; to diagnose accurately the presence or absence of a dorsalis pedis pulse;—to select at random a few examples of conditions that the physician be he surgeon, psychiatrist, internist, ophthalmologist or other medical practitioner, may encounter at anytime.

There are a number of emergency conditions to which any of us must be able to respond on a moment's notice. They may occur on the street, in the home next door, on the train or bus or in the hospital or office. Such conditions as massive bleeding, shock, "heart attacks," syncope, convulsions, poisoning or drug overdosage and fractures are among these. Certainly, the victim of any of these conditions has a right to expect any of us to handle such emergencies competently.

Thus far, I have spoken of what any phy-

sician should be able to do. I am particularly concerned, however, with what one group of physicians—psychiatrists—can and are doing. It is my impression that, while the situation has vastly improved since the days of Weir Mitchell (6), who complained to us 67 years ago of being unable to find either a stethoscope or an ophthalmoscope in one mental hospital where he was called in consultation, it could and should be much better than it is in many places.

It has been rather disturbing to me to learn how quickly the general medical knowledge and skills of many young psychiatrists seem to deteriorate. For a number of years, when I have visited a psychiatric training center and have been asked to talk with residents, I have asked them to identify themselves as to the length of time since their internship and the number of years they had been in residency status. I have then mentally grouped them according to whether they have been in psychiatric training more than 18 months or less. In the course of my discussion, I have posed a series of questions to them. Representative of these questions are the following :

One of your outpatients who is a diabetic and on insulin has just been brought in unconscious. What would you do and why ?

You have called a cardiologist in consultation. He reports that he finds A-2 greater than P-2. What is he talking about and what may it mean ?

You notice unilateral ptosis on examination of a patient. On closer examination you find a pinpoint pupil and enophthalmos in the same eye. What do you think has happened ? What other phenomenon would you expect to find ?

A patient tells you his left leg is slightly shorter than his right. How would you determine if this is so or not ?

I am always concerned to find that the residents in the first 18 months do very well answering the questions and that they seem to enjoy the session ; but the senior residents are much more likely to do poorly, and not infrequently they are bored with the whole business. The senior residents often wonder what all this has to do with psychiatry anyway. Members of the faculty will frequently remark that I expect too much of the residents. They are there to learn the details of

psychiatry and that is a subject which should and does consume all of their thinking. It will be time enough to brush up on other aspects of medicine should the need ever arise, after they are through their training and have passed their Boards. To this observer, such an attitude is ominous for the future of the psychiatrist as a physician.

Psychiatry is a fascinating and absorbing subject, as all of us can testify. To the resident it is a new territory to explore, and he has great enthusiasm for it. Because of this he will tend to put aside all else to learn everything he can of this complicated and challenging specialty which he has chosen for his life work. This is but natural, but it is the obligation of his teachers to see that he remains firmly grounded in medicine, and that he continues to practice what he has learned.

Of course, what has been said about the psychiatric resident retaining his medical skills applies with equal force to his teachers, for they shape his learning and his attitudes.

Would it not perhaps be revealing to poll the membership of this Association to ascertain the last time each had taken a post-graduate or refresher course in any phase of medicine except psychiatry ? I greatly fear that the number who had done so in the past 5 years would be a very small proportion of the membership. There is something inconsistent in this. As an Association, and as individuals, we have quite properly urged our non-psychiatric colleagues to learn more about psychiatry and themselves to handle many of the problems they encounter, thus expanding the services available to patients who need them. But why do we not apply the same logic to ourselves ? Is there some special quality in a psychiatrist that justifies his exemption from the rule "physician first, specialist second" ? Do not our patients come to us in the first instance because we are physicians ?

I submit that to claim exemption from the role of physician in the community can only contribute to the insidious blurring of the image of psychiatry as a part of medicine and of its practitioners as full members of the medical fraternity. Not long ago, for example, in one community it became necessary for the local medical society to establish

a 4-hour duty roster for nights and week ends in the emergency room of the local hospital because of a sharp and sudden depletion of the house staff. All members of the society *except the psychiatrists* agreed to such an assignment in rotation. The duty consisted primarily of identifying the condition of the patient, instituting minimum emergency measures where necessary, and calling for an appropriate physician to attend the case. The psychiatrists maintained that they felt themselves so unfamiliar with what would be required of them that it would be in the best interests of the patients if they were excused. On this basis, they were not given assignments, and quite properly so. To me as a member and as President of the American Psychiatric Association, however, it was disconcerting to realize that psychiatrists in that community were so removed from the main stream of medicine that they—and they alone—had to claim exemption from the role of physician in this emergency situation.

If psychiatry is a medical specialty concerned with the prevention, diagnosis and treatment of mental and emotional disorders, how can psychiatrists allow their basic medical skills to fall into disuse—to rust to the point that they are unusable on demand? We are a uniquely valuable resource for a troubled society precisely because we are physicians. We, and we alone of all those who are concerned with mental illness, are equipped and required to evaluate and assume responsibility for the care of the total individual. There are others who possess the ability to diagnose and treat the physical aspects of the problem. There are still others competent to identify, modify and improve specific psychological and sociological components underlying the onset and affecting the course of mental disorders. But only the psychiatrist is expected to bring together in one person knowledge and technical ability in all of these fields. In fact, while we were as well prepared in medicine at the time of graduation as any of our contemporaries, the great majority of us have not acquired as detailed or thorough background in the behavioral sciences as those who have devoted their lives to mastery of these disciplines. Most of us are not specialists in any one of

the behavioral sciences; rather we are generalists in these disciplines, with the added quality of possessing competence in medicine which other behavioral scientists have not acquired. This qualitative difference, I suggest, is not usefully viewed as a matter of status or rank. It is more properly considered in relation to the role that society assigns to us. This difference is the justification for defining psychiatry as a branch of medicine. One wonders, however, if the incident I have cited is not an isolated case, what justification we have for our position. If one deals only with the psychological or social phenomena of those who present themselves for relief, if one thinks not in terms of the whole individual, if one is not always on the alert for manifestations of malfunction in any organ system, if one is no longer competent properly to identify such pathology and effectively to deal with it either himself or by wise referral, how does one qualify to employ a medical procedure? Under the circumstances how is the psychiatrist to reflect the substance in the medical degree he holds? How does he differ from the nonmedical practitioner of psychological or sociological procedures? The latter is, at least, not expected either by his client or by society in general to possess medical skills.

My plea is that the psychiatrist must retain his basic competence as a physician and that the entire course of his specialist training should be designed to assure that he does. This is largely the responsibility of his teachers not only in general psychiatry, but also in its subspecialties as well. This responsibility must be discharged, it seems to me, both by example and by providing the environment that will motivate the student. If the teacher has scant interest in medicine *per se*, it is to be expected that his students will reflect this attitude.

Additional motivation might be provided if the student knew that at the time he stood for his examinations before the American Board of Psychiatry and Neurology, he could expect the examiners to investigate his grasp of the fundamentals of general medicine as well as of basic and clinical psychiatry and neurology.

The teacher by no means bears all the responsibility, however. The psychiatrist

also has an obligation to his patients and to himself to continue to be knowledgeable in the broader field of his basic profession. There are graduate and refresher courses given frequently, but even more immediately available are the opportunities provided by the meetings of his medical society. Much is to be learned not only through the medium of formal papers and discussions, but also through informal discussions before and after the scientific session itself. I have said during this past year that I feel it is important that each of us takes an active part in our medical society. Such participation offers the opportunity to keep abreast of general medicine and to present ourselves as a *bona fide* part of the medical community.

If we are ever to break down the walls which have isolated us from the rest of medicine, it must be possible for our non-psychiatric colleague to expect as much of us *vis-à-vis* his field as we expect of him in the realm of psychiatry. Weir Mitchell(6) spoke of this at the 50th anniversary of our Association, and Gregg(5) addressed himself to it at our centenary. Perhaps, speaking to you only 17 years after Gregg, I am expecting too much too soon; but, when I view the breath-taking progress of those years, I am sanguine that psychiatry and the rest of medicine are about to become as one.

Some of my colleagues with whom I have discussed my concern have felt that I am putting too much emphasis on the physical aspects of psychiatry. They have pointed out that a psychiatrist must be many things—a physician, a social scientist, an anthropologist, a psychologist. I agree whole heartedly. I would point out, though, as I have said above that our deficiencies in many aspects of psychology, in the social sciences, in anthropology, and similar fields can in a measure be compensated for by scientists working with us who are thoroughly trained in those fields. Since only the psychiatrist, of all those concerned with mental illness is a physician, upon his shoulders, and his alone falls the responsibility for the *total* evaluation of the patient—physical, psychological and social; and therapy, conducted or prescribed in the light of such an evaluation, is his singular responsibility.

Just as I have been told that I expect too

much of residents, so, also, have I been told I demand too much of psychiatrists generally. I do not feel this is so. Rather than demanding too much, I ask only the minimum; and I ask no more of you and me than I ask of any physician.

Some time ago, I sent to the officers of each District Branch, for the information of their members, the verbatim transcript of my testimony before a Committee of the American Medical Association. In it I said it was my opinion that a physician, whatever his specialty, who cannot make reliable psychiatric diagnoses and conduct therapy as skillfully as he carries out any other medical procedure outside of his specialized field, was not properly prepared to practice medicine. I have not heard one voice from this Association raised in dissent. I assume, therefore, that you are at least in general agreement with the position I took as your representative. But what is sauce for the goose is sauce for the gander. Are you equally in agreement when I say that by the same token no psychiatrist is qualified to engage in practice unless he can demonstrate equal skill in the diagnosis and treatment of medical conditions to that we expect of our non-psychiatric colleagues in the field of psychiatry?

By no means do I imply that we should attempt to deal with those conditions requiring specialized skills beyond our competence, but only that we must always be physicians first and psychiatrists second. It is not enough that we be physicians in name only.

What I have said here has been said out of a sincere devotion to the best interests of the mentally ill who are our primary responsibility, and to you, my colleagues, whom I have tried to serve to the best of my ability. This field of medicine which is our special trust, this psychiatry which we try to understand and to apply, is so important for the physical, social and psychological welfare of mankind that our best efforts and most skillful services are the minimum we can offer.

Although I have addressed myself to some of the problems, as I see them, of the psychiatrist as a physician, it has not been my intention to minimize other aspects of his responsibilities to his patients or his community. The scope of what is required

of him is so broad that he may at times despair of fulfilling all that is expected of him. The job is difficult and intricate, and I know of no one, knowledgeable in the field, who has recommended our calling as an easy or simple way of life; but for all that, the satisfactions are so great, the sense of worthwhile service is so profound, that were we to choose again we would still select the same career—and this with the full knowledge that the complexities and the demands of our job are increasing with each new bit of knowledge about man, his behavior and his environment.

Alan Gregg(5) painted the picture of the future of psychiatry as only that great and wise physician and scholar could do when he said :

"Before the two hundredth anniversary of this Association, psychiatry will find great extensions of its content and of its obligations. There will be applications far beyond your offices and your hospitals of the further knowledge you will gain, applications not only to patients with functional and organic disease, but to the human relations of normal people—in politics, national and international, between races, between capital and labor, in government, in family life, in education, in every form of human relationship, whether between individuals or between groups. You will be concerned with optimum performances of human beings as civilized creatures."

This amalgam of new roles we are being called on to fill adds to the danger that our basic medical responsibilities may receive insufficient attention. We must not allow our preoccupation with new roles to jeopardize our foundations in medicine.

As we grow in wisdom and in knowledge, as we become able to fit together more and more pieces of that most fascinating of all puzzles, the psycho-bio-social entity known as man, that which is required of us will increase also. Our role becomes more complex and our job becomes more exacting and demanding. We cannot fulfill these demands upon us by giving short shrift to any of the elements of our profession and least of all to those that permit us the title of *Medicinae Doctor*. Just as the son is the child of his father, so is psychiatry the child of medicine. It is essential to our maximum usefulness, stature and effectiveness that we remember, cherish and build upon that heritage. What ever else we are or may become, we are of the lineage of Hippocrates. By education and by commitment we are practitioners of the healing arts, while giving particular attention to psychological medicine.

ROBERT HANNA FELIX
Eighty-Ninth President, 1960-61

A BIOGRAPHICAL SKETCH
FRANCIS J. BRACELAND, M.D.¹

There is a kind of Character in thy life
That to th'observer doth thy history
Fully unfold.
Heaven doth with us as we with torches do. . . .
. . . Not light them for themselves.

— Measure for Measure. —

Character, it is said, like porcelain, must be printed before it is glazed, but once burned in there can be no change. As to the printing, many diverse materials may be utilized. Walter Pater wrote of it long ago: "How insignificant," he said, "seems the influence of the sensible things which are tossed and fall and lie about us in early childhood, how indelibly, as we discover afterward, they affect us, as they secure themselves upon the smooth wax of our ingenious souls." This could well have been written prophetically about the 89th president of the American Psychiatric Association, for, as one notes the influences that fell about him, it becomes evident that they would lead him inevitably to medicine and, eventually, to a form of public service which would call forth and utilize all of his attributes.

Though Voltaire stated that he who loves his country well has no need for ancestors, Robert Hanna Felix had been thoughtfully provided with plenty of them. They came from all directions, with a profusion of physicians among them. There were Whigs and Tories and rebels of every size and description. There were several big ones, including Robert Hanna, Surveyor General of South Carolina under George III; yet the Revolution found him fighting for the colonists with a price upon his head. In the other "unpleasantries" in which the nation engaged, the boy's ancestors thoughtfully lined up on both sides, thus giving their descendant entrée into all manner of "posh" societies on both sides of the fence and enabling him to be at one with whomever he

is talking to. Like Seneca, however, Dr. Felix believes that the origin of all mankind is the same and it is only a clear and good conscience that makes a man noble, for that is derived from heaven itself.

Robert Hanna Felix was born in Downs, Osborne County, Kansas, deep in the wheat country, on May 29, 1904, to T. Ovid and Neva Trusdle Felix. His father, known as T. O., was a country doctor; his mother, daughter of a pioneer physician of the West, had studied music in Boston. There was one beloved sister, Mary Bryning Felix, who eventually married her brother's college roommate. The lad graduated from Downs High School in 1921 and then worked for a year to help with the family exchequer, for the pay of country doctors was in comestibles, respect, and affection, rather than in U. S. currency. He entered the University of Colorado in 1922 as a student in journalism, having won an essay contest, and visions of emulating Richard Harding Davis stirred within him. Before the year was out, however, he turned to biology, a temporary way station on the road to medicine, for fate had destined him to become a fifth generation physician in the Felix-Trusdle ensemble.

He entered the University of Colorado Medical School in 1926, completing his work with honor in 1930. As had many a good man before him, he worked to support himself—he drove the hospital ambulance at night. On the side, it is whispered, he acquired a facility for drawing full houses and filling inside straights. Externship, then internship at the Colorado General, and then the decision about residency. He leaned

¹ 200 Retreat Ave., Hartford 2, Conn.

toward OB but he cast about too, for stipends and maintenance were important, as the country was in the depth of "the depression." To his dismay, he was accepted for training in 3 disciplines in 3 different places and all within one week.

A Commonwealth Fellowship put him under the tutelage of Frank Ebaugh and that event, he says, "was one of the most important experiences in my professional career. Ebaugh was a superb teacher, a tough task master, and an inspiring mentor. We were steeped in community psychiatry and a philosophy of public service."

THE PRINTING

Every man who aspires to greatness is unique; some forces touch only lightly upon him, while others leave a lasting imprint. Among the forces which marked Robert H. indelibly were his parents, his wife, and two of his chiefs. The *pater familias*, before he studied medicine, was an historian and a clergyman. He read widely in modern and ancient languages. Bob's mother was an accomplished musician and, thus, the boy was exposed to the best in music and books. T. O. began his medical career on horseback, graduated to a buggy and, finally, to a horseless carriage. There were numerous tales of his homespun diagnostic skill and his boy rode with him and saw evidences of it first hand. The people knew Robert as "Little Doc" and, thus, he was always immersed in a clinical atmosphere and from childhood was permitted to listen to heart and breath sounds through a stethoscope. All of this imprinting accounts for his image of himself as a physician—he had it then, he has it now, and will always have it, no matter how far from the bedside he strays.

From the age of 7 his summers were spent on a farm and these were some of the happiest days of his life. He talks of threshing machines and of oiling and repairing them. He remembers the sweat of the hot days in the wheat fields and he can grow lyrical about what it was like to wake up early on a cold Kansas morning, when snow was on the ground and all seemed blue, the wind was quiet and the sun rose slowly. He can recreate for his listeners his love for the snow, for the earth, and for

everything that was Kansas. Through his love of the land and his pride in his family, he has an almost mystical sense of being bonded to the country.

He can become nostalgic about Ebaugh and his hypomanic drive, which was communicated to all of his colleagues. Of him Ebaugh says: "His nuisance value was considerable. He would ask me the cause of schizophrenia and push me regarding definitions of everything . . . He was a classical hypomanic, so we had many things in common." During his first year of residency, the young neophyte underwent another experience which still influences him. Just as Petrarch saw Laura, Bob saw Esther Wagner (Peg), a member of the nursing staff of Children's Hospital, and neither poet was the same ever after. Bob's descriptions of "Peg" outdo by far the poetry of his descriptions of Kansas. She was ill for a while, so their marriage was delayed until June, 1933, and then, believe it or not, they were married in Loveland, Colorado. Everyone who knows Dr. Felix knows of the place she holds in his life, one shared only by Kathy, a daughter, and each is a joy unto the other.

The residency was over in 1933, the depression was not. A variety of circumstances placed the young psychiatrist at the Department of Justice Medical Center in Springfield, Mo., as a commissioned officer in the U. S. Public Health Service. The next duty station was the Narcotic Hospital at Lexington, Ky., in the beautiful blue grass country, and here his wife completely regained her health. He advanced rapidly in this happy setting and in 1941 was assigned to the Johns Hopkins University for training in public health. By this time, too, he was President of the Kentucky Psychiatric Association, a forecast of things to come.

This training in public health was a powerful influence for the young doctor, for here he saw for the first time the necessity of studying and understanding the epidemiology of mental disease and the essential role the social and behavior sciences play in the picture. His entire outlook on psychiatry changed at that time. He graduated with a Master's degree and as the war broke out he closed the year with orders to the Coast Guard Academy in New London to inaugurate a complete program for the se-

lection, counselling, and therapy of officer trainees. It was here that the young officer was to bloom but, before chronicling his stay, there are several other influences to be mentioned.

Among the seniors Bob had met, Walter Treadway and Lawrence Kolb, Sr. stood out in his affection. Both had been chiefs of the Mental Hygiene Division and Dr. Kolb had recommended him for public health training. Dr. Kolb had also had the seminal ideas for a Mental Health Institute in 1938 and recently, as Dr. Felix was being honored as President of the APA by his staff and friends, he reached into the group, called Dr. Kolb to the fore, and spoke of him as his mentor and the man who had laid the foundation for the development of the NIMH.

No account of these years would be complete without mention of the second chief who was to greatly influence Bob's life, Surgeon General Thomas Parran. Of him Bob says :

He was an inspiring leader who believed in giving his staff their assignments and in letting them alone. Always available for consultation and advice, he was most generous with both, if asked. From the start I had a very great admiration for Tom Parran and a sincere affection for him also . . . His insight into the mental health needs of this country was phenomenal . . . The program would never have gotten off the ground without his support with the Bureau of the Budget, the Department and with Congress.

COAST GUARD

The Felix saga at the Coast Guard Academy deserves a lengthy chapter, but editorial demands require that it merely be touched upon. How he placed psychiatry solidly in the program, how he gained the confidence of the officers, staff, and line, how he eventually became a highly respected physician, confidante, and model for young medical officers, all must be passed over lightly. His program there was run with integrity with a capital "I," as it was before and has been since, and here is the cornerstone of his success. It was at New London, too, that he worked closely with "Vesty," Dr. Seymour Vestermark, he of great and good heart, a lovable, dedicated

physician and public servant. No biography of RHF would be complete without mention of him. It was to Vesty that he looked with filial glance and there was a mutual respect and loyalty between them. Everyone knew of the famous triple play team : Bobbit to "Vesty" to Felix. If one wanted something done, the best way to have Bob do it was to convince "Vesty." Frequently it required Bobbit to do the original convincing. When "Vesty" died all who knew him were distressed but it was an especially sad blow to his chief.

WASHINGTON

On his 40th birthday, May 29, 1944, Dr. Felix was ordered to Washington as Assistant Chief of The Hospital Division. This was obviously for the purpose of looking him over and 2 weeks before Dr. Kolb retired he was told he would be Chief of the Mental Hygiene Division. All of his accomplishments since then are a matter of public record.

The time was right to strike a blow for mental health and the Mental Health Act was conceived, worried about, corrected, and presented to Dr. Parran for his aye or nay. The details of all of this and the people involved and all the hopes and fears and eventual successes are too vast to chronicle here. The bill was passed and was signed by the President on July 3, 1946. Congress adjourned the next day. The National Mental Health Act was official and in business, but without money, since there was no time to obtain a supplemental appropriation.

Bob was advised by the skeptics and cynics that he had been given "the business." He had a law but no money and Congress had gone home. There would be a new Congress next year and they were not bound by the other's actions. Dr. Parran consoled him and appointed a National Advisory Mental Health Council and now money was needed for it to have a meeting. Felix made the rounds of the foundations. The executives were sympathetic, but skeptical, until finally the Greenwood Foundation, now in limbo, put up \$15,000 for the meeting. There is something paradoxical about the fact that a small foundation staked an agency which would distribute millions, if

we had the space to consider it in detail here.

On December 3, 1945, another event of world shaking importance occurred. Mary Katherine Felix (Kathy) was born and, as Walter Treadway says, she became Bob's greatest hobby. Kathy, in turn, sees no need for any fuss; she just declares him "the best Pop in the world."

When Congress convened in 1947 the first appropriation came through, amounting to \$1,900,000. Thirteen years later the appropriation was to be \$100,900,000. On April 1, 1949, the Surgeon General abolished the Mental Hygiene Division, created the National Institute of Mental Health as one of the National Institutes of Health, and named Dr. Felix Director. The Institute became an essential arm of the Service and in March, 1957, he was promoted to Assistant Surgeon General, Rear Admiral, and Principal Officer of Service for Mental Health and Psychiatry. The amount of good this Institute has done for the cause of mental health is incalculable. To even hint at the scope of its research and teaching efforts would be far beyond our purview here. Without its farsighted planning and help, the whole psychiatric picture in this nation would be one bordering on chaos.

AND THEN THE MAN HIMSELF

Often, as the record of a man unfolds, one sees how, wittingly or unwittingly, he is the artisan who constructs his circumstances. He may twist and turn, now going this way and then going that, but eventually he arrives at the niche which was destined for him. If he can tolerate frustration without being weighed down, he can make that niche reasonably liveable and, should he possess the qualities of dedication, discipline and courage, then he and the niche might become comfortable indeed. Love and duty will protect him and constitute the boundaries which keep him in safe territory and, should he by chance be possessed of a touch of humor to lighten the environment about him, then he and those who work with him will be thrice blessed. This is how the staff members of the National Institute of Mental Health consider themselves. There is no unwonted or sickly adulation; they feel they have a clear perception of the man who

heads their organization. They know all of his faults and can recount them readily, but they regard him with respect and a genuine and deep affection, and love him with his faults and in spite of them. They recognize that he does not like being second best in anything; he wants the job done rightly and the spirit of being best is a part of his style of life. His wisdom and the soundness of his objectives, however, prevent this from being in any way unpleasant.

When the Institute was small, "The Chief" knew everyone personally. The same interest that he displayed for the staff and the Coast Guard, he displayed for Institute personnel. He has the ability to understand the other person's point of view and the same ability to make every person he talks to feel that he is a teacher who has something to impart, which otherwise Bob would not have learned. This is an art, for he must encourage people who have something to contribute; yet he knows he may eventually have to sit in judgment upon that contribution.

It is the consensus that Dr. Felix is a learned man. He knows well his own field of endeavor. Sitting as he does in the center of a group which is constantly receiving reports of progress in the different aspects of the field and being briefed by all and sundry, it is difficult to think of anyone better informed in the field of psychiatry. Certainly, when he is fully briefed and prepared to appear before congressional committees, there is no one better informed, for, like the astronaut who eventually will climb into the capsule, he has been in training and preparing for the day when he will take flight up "on the hill," prepared for all eventualities. At these times he is under tremendous tension; symptoms appear; he is frightened and scared and, yet, there is a certain security about his knowledge and a sureness of what is going on; he believes in it and, when he goes up there, he is the Institute.

There are other subjects besides medicine and psychiatry in which Felix has an appreciable knowledge and a high degree of interest. He knows and understands music, he reads widely in the field of literature, and he is somewhat of an expert on the Civil War. Most psychiatrists and many leaders in

other fields have had occasion to sit upon committees and have watched this man work. Their first reaction is one of wonderment that anyone could have been chairman of such high-powered committees for 14 years, passing judgment upon the worth of applications for grants and encouraging the opening up of new directions in psychiatry, without having a whole host of sharpshooters after him.

Next, they are in admiration of his qualities of associating himself in some way with everyone in the area, no matter who they are or where they come from. He has some relationship with each part of the country and some investment in each calling or profession he encounters. If he is speaking before a congressional committee on juvenile delinquency, he recalls his own days as a "juvenile delinquent," for he stole watermelons from farmers! Soon the committee members remember their own youthful peccadillos and then Bob moves into a discussion of the mobilization theory of human behavior. The session ends with everything having been accomplished but taking up a collection. He had started with the small and simple, and ended on a note much more sophisticated. Dr. Parran once spoke of him as having "the ability to take a broad geographic view." One shudders to think what might have happened had a man broad of beam rather than broad of view landed in that job and decided to play it safe and not take a chance on getting into trouble. Had this happened, we would still be back where we started from ages ago.

Many of the present day developments in psychiatry have taken place because of the leadership and assistance of the National Institute of Mental Health and much of this success stems from the vision and unflagging devotion of Robert H. Felix, who has persistently worked toward the application and expansion of the public health approach to mental illness and mental health. His leadership has been directly instrumental in inspiring the confidence of the Congress, the Executive Branch of the government, his superior officers, and his colleagues. One nationally known scientist says: "I can tell you there exists in NIMH an *esprit de corps*, which stems directly from Dr. Felix, that is unique in any organization of this

size. I have often pondered how he can know so much about the various programs, maintain the fantastic schedule that he does and be as effective as he obviously is. One of the basic reasons for his success is his rare ability to concentrate only on what he is doing at a given moment and then relax at every possible opportunity. He is a real father figure to the National Institute of Mental Health and he apparently has that rare virtue of leaving all of his troubles and not taking them home with him."

His hobbies amuse everyone. He goes into everything with such enthusiasm that he is unaware that he is exaggerating. The modest victory garden he had during the war, the roses he grew in Washington, next the dahlias! Then the woodworking in the basement—he is tooled up to make B-59's. The estimate is 50 dollars worth of tools for every dollar project. There are amusing anecdotes, too—the "tomcat" which had kittens, the purple exclamations when the admiral's key was down on the intercom system—but we can't go into them. His intimate friends see him as a man of open heart, great warmth, and a quality of humor which has endeared him as "The Kansas Windstorm."

Honors have been plentiful, as might be supposed. He holds Doctor of Science degrees from the University of Colorado and Boston University, and Doctor of Laws from The University of Chattanooga and Ripon College. He is a diplomate, and member of all of the psychiatric and Public Health societies that he should be, and is a certified mental hospital administrator. He was Chairman of the Budget Committee of the APA for 10 years and Treasurer for one. He has represented his country abroad and at home in many capacities in the Public Health Service and these, plus his many honorary societies and fraternal organizations, constitute a formidable array, too numerous to mention here.

His deepest loves are his family, his country, his work, his church, and his friends, and all of these should be put first. He is a vestryman in the Episcopal Church and the class he runs on Sunday about everything in particular has to put out the SRO sign. Through all of this runs a deep sincerity and a desire to help people. It is difficult to

write his biography ; it sounds so much like a paeon of praise, even though one starts without that intention. There is no doubt, however, about his genuine sincerity and his many abilities ; if he has any enemies, they are simply potential friends

whom he has not had time to level with as yet. As we survey this rather breathless, but wonderfully productive career, in which a dedicated man carried the lamp of sane benevolence chiefly for "the weaker by the wall," we can say to him and of him :

The secret consciousness

Of Duty well performed—the public voice

of praise that honors virtue and rewards it

All of these are yours.

CULTURE AND MENTAL ILLNESS ¹

ASHLEY MONTAGU, Ph.D.²

It is not, I think, too often pointed out that contemporary psychiatric theory and the development of modern cultural anthropology evolved at about the same time. That the cross-fertilizing effects of the two fields have been considerable and mutually beneficial has been gratifyingly clear for more than a generation. That the reciprocal interstimulation will continue in depth on an ever-widening horizon is already evident. The mental health of both disciplines will, in the future, depend to a considerable extent on this continuing agreeable relationship. Something of what has thus far been achieved as a result of the ethno-psychiatric interdisciplinary approach to the study of mental health and illness will, I hope, be made evident in what follows.

With this obeisance to the ceremonial phase of the discussion, as it is called in anthropological circles, we may address ourselves to the more profane part of these ritual proceedings.

We are to discuss culture and mental illness. Let this be taken to mean that I shall not only be discussing the influence of culture on mental illness, but also the influence of mental illness upon culture. The latter is an approach which, it seems to me, has received altogether too little attention.

Perhaps we might commence with some working definitions of our terms. By *culture* we understand the man-made part of the environment, man's symbols, ideas, values, traditions, institutions, pots and pans, and technology. As the late Sir John Myres put it, culture is what remains of man's past working on his present to shape his future.

By *mental illness* we may perhaps understand a more or less gross, more or less persistent failure of social adaptation. It should be made clear at the outset that the term *mental illness* as used here refers to functional mental disorder, and not to organically originating mental illness. It is understood that genetic factors and, probably,

prenatal factors are each classes of variables which, under certain cultural conditions, are capable of making a significant contribution to the incidence of mental illness. By *mental health* we shall mean the ability to love and to work, or if you like, the balance between anxiety and its resolution.

It should be understood that with the development of human culture man has entered a new zone of adaptation, in which, through the socialization process, he learns what is expected of him and what he may expect from others. He internalizes the norms and acquires a working knowledge of his culture as a whole. While no one in any culture ever develops a mastery of every aspect of the culture, in different cultures and in different segments of the same culture there exist significant differences in both the quantity and the complexity or quality of the cultural variables, a good many of which the average member of such a culture is able to command. In general nonliterate cultures (the so-called "primitive" cultures) are both quantitatively and qualitatively less demanding of their members than literate cultures, at least, this would appear to be so. The individual is simply not assaulted by so many and so various stimuli or expected to know and do as much as the average member of literate cultures.

It is an open question whether we do not have in this difference one that is in itself a significant factor in producing the differences in the frequency and distribution of the various forms of mental illness. Is it possible that the sheer weight, recurrence, and complexity of the innumerable variables which the person has to master in a complex society constitute if not the sufficient conditions, then at least some of the necessary conditions in contributing to the incidence of mental illness of various kinds in societies culturally so weighted? The strain of life under highly complicated and stressful conditions of existence can play havoc with the human organism, and it seems to me reasonable to suppose that the

¹ Delivered as the Dinner Address at the Eighth Annual Psychiatric Institute of the New Jersey Neuro-Psychiatric Institute, Princeton, N. J.

² 321 Cherry Hill Road, Princeton, N. J.

less stressful a culture is upon the individual the less likely is there to be mental illness in such a culture. The evidence of cultural anthropology supports this relationship.

In every culture there probably exist differences among individuals of a genetic and constitutional nature in the ability to adjust to the stresses and strains of the load of cultural competencies they are required to carry. But when that has been said one has said very little, for the role played by the genes is extremely difficult to measure, and constitution is itself the dynamic expression of the interaction between genetic and environmental factors. It is a massive task, which no one has yet undertaken for any population, to tease out and determine to what extent genes and to what extent environmental influences are responsible for the individual's response to the cultural load which is placed upon him.

The environmental factors begin to be operative upon the organism from the moment of conception, and even before. By "before" I refer to the influence exercised by environmental factors upon ova and sperm before conception. We know that environmental factors operative during the prenatal period are capable of producing what Pasamanick has called a *continuum of reproductive casualty*, which ranges all the way from death to transitory minimal cerebral defects, I believe that in connection with mental illness we shall have to consider the possibility that different cultures provide the conceptus with different prenatal environments sufficiently different to affect the individual's subsequent behavioral development. The influence of prenatal factors upon behavioral development is a fascinating subject which has only just begun to come under investigation. The cultural aspect of the subject remains virtually completely untouched. Neither the anthropologist nor the social biologist, nor, it should be added, has the psychiatrist, devoted any significant attention to this area of human experience. And yet the experiences of the human organism during the first 267 days of its life *in utero* may turn out to have a highly important bearing upon the epidemiology of mental illness. The culturally determined differences in the pregnancy experience of women in different cultures may

well result in differences in predisposition to mental illness of the individual in different cultures.

There is evidence that in our own culture babies born to mothers who have had disturbed pregnancies, at birth already exhibit behavioral disturbances. I refer to the work of Sontag in this country and of Stott in England. Intrauterine convulsions of the fetus have been described in mothers who were emotionally disturbed, and there is evidence that the fetus can be sufficiently emotionally disturbed *in utero* to develop a peptic ulcer and be born with it. May it not be that the differences in cultural experience during pregnancy in different cultures constitute a significant factor in the etiology of mental illness?

A period very differently handled in different cultures and which, it may be suggested, is possibly critically productive of differences in the predisposition to mental illness is the first year of postnatal life. There is a good deal of evidence which indicates that the first postnatal year, and especially the first 6 months, is a developmentally very much more sensitive and vulnerable period than has hitherto been supposed, and that cultures which fail to recognize this are likely to exert a damaging effect upon the development of the individual. The evidence is both interesting and convincing, and a good deal of it has been summarized in Bowby's WHO report *Maternal Care and Mental Health* and in my own *The Direction of Human Development*. Recently I have come to view man's gestation period as not being completed till about 8 to 10 months after he is born, that is, about the time when he begins to crawl. *Uterogestation* is terminated, in my view, principally because the size of the fetal head reaches the maximum size consonant with its ability to pass through the birth canal. The fetus must be born when it is born if it is to survive, but its gestation must continue outside the womb, a process which I have called *exterogestation*, similar to that of the marsupial. If this interpretation of the facts is correct then it should be clear that the human infant during its first year is in a very much more precarious position in relation to the world into which it is born than we had previously supposed.

Mother and child continue to form a symbiotic unit at birth. Birth is wrongly interpreted as an interruption of that unity, a unity which should continue for many months after birth, and which both mother and infant are reciprocally designed to continue. Contact with the mother's body, the baby's visual experience of that body, the support she gives, the breastfeeding that should continue for at least 9 months, all these are indispensably necessary conditions for the wellbeing and healthy development of the infant. Any culture which discourages its mothers to behave in this manner is likely to contribute in a major way to the predisposition to mental illness in its members. The extreme dependency of the infant must be met with all the responses it calls for. Unless these are provided the results may be subsequently catastrophic. Whether such satisfactions are afforded the infant is a matter which in every society is culturally determined. Hence, here is a basic relation between culture and the incidence of mental illness.

At this point it is perhaps necessary to say that no culture is completely homogeneous, in the sense of providing or being the same for each of its members. There are differences of status, roles, class, caste, and the like. There appear to be interesting differences in the frequencies, and in some cases even in the kinds, of mental illness, associated with such social differences. This has been clearly demonstrated in Hollingshead and Redlich's 10-year study of the New Haven community, *Social Class and Mental Illness*. Among the 5 social classes distinguished by these investigators, the results showed "The lower the class, the greater the proportion of patients in the population." Class differences in type of mental illness followed the rule: "The higher the class the more neurosis and the less psychosis, or inversely, the lower the class the more psychosis and the less neurosis." But, as Hollingshead and Redlich point out, these differences may be an artifact of the different ways psychiatrists are utilized by the classes. Also genetic and constitutional factors may play a role. However this may be, Hollingshead and Redlich have made out a good case for the view that "who becomes a psychiatric case, particu-

larly if neurotic behavior is involved, depends in large part upon where one is in the class structure." Similar findings have been reported by Kaplan, Reed, and Richardson on the prosperous Wellesley, Massachusetts population, and the "below average," "Whittier Street area" of Boston.

Class and caste, and even religious differences within any culture, often become as significantly different from each other as are the differences between different cultures. This is not a new observation. Anyone of any experience of life has repeatedly made it, and it was quite clearly stated in 1845 by that remarkable anthropologist Benjamin Disraeli when, in his programmatic novel *Sibyl*, he says, "I was told that the Privileged and the People formed Two Nations," (Bk. Iv. Chap. 8). The "Two Nations," of course, being the upper and lower classes of 19th century England.

In America Jurgen Ruesch finds that the preponderance of psychosomatic conditions in the lower middle class, "the culture of conformance and excessive repressive tendencies," may be explained as due to the lack of expressive facilities, hence the solution of psychological conflicts through physical symptom formation. In the lower classes, hostility frequently tends to express itself through accidents, fractures, and traumatic disease. The upper classes, "with overbearing superego traditions" manifest a relatively large frequency of neuroses and psychoses, especially of the manic-depressive type.

Tietze, Lemkau, and Cooper in their study of the relation between mental illness and socioeconomic status in America found that schizophrenia tends to be the mental illness most common among social isolates, such as unskilled workers, farmers, or lone urban residents and manic-depressive illness being most prevalent among professional, religious, socially prominent, and other groups of persons, who have strong idealistic, interpersonal, and community involvements.

Every culture requires the acceptance of a certain number of fundamental values. This requirement in many cultures, if not in all, is itself generative of stress in some individuals who, from constitutional, temperamental, or other reasons are unable to ad-

just to such values. In some cultures, such as our own, the attempt is made to socialize the individual in irreconcilable and mutually conflicting values. For example, the accidents of history have made Americans the heirs of the Hebraeo-Christian tradition ethically, and of successful competition within the framework of American social evolution. A great many individuals break down from the effects of unsuccessfully struggling to reconcile the Sermon on the Mount or its equivalent with the principle of competition. Others find no difficulty in harmonizing the two. As a consequence of carrying the burden of such conflicting values why do some individuals break down, while others do not, exhibiting, at most, only minor symptoms? Until a great deal more research has been done it will not be possible to return a satisfactory answer to this question.

Where the culture provides institutionally sanctioned outlets for the reduction or resolution of the stresses it creates, or where the individual can find these for himself without too much strain, mental illness is likely to be avoided by those who can utilize these outlets. Those who cannot are likely to become behaviorally ill under the strain.

In a small atoll society of 250 people such as that of the Ifaluk in the Central Carolines of Micronesia, where the climate is pleasant, land and sea produce an abundance of food, and the work required of anyone is neither long nor strenuous, it is not difficult for anyone to live up to the paramount values of the culture: kindness, cooperation, and nonaggression. Spiro tells us that no one could remember a single instance of murder, rape, robbery, or fighting (with one exception). Hostility finds an outlet through individual and cultural fantasy, that is, through dreams and legends. Religion provides another outlet for hostility through its good and bad ghosts (*alus*). But even on Ifaluk mental illness sometimes occurs, and there were 3 such cases in which, interestingly enough, a dominant characteristic was the subdued aggressiveness of each affected individual. Spiro attributes the repressed hostility and anxiety of the Ifaluk individual to the peculiarities of Ifaluk infantile experience—largely the morning bathing of the helpless infant in

the cold water of the lagoon—water so cold that adults avoid it until the sun has warmed it and it becomes bearable. All else is over-indulgence until 4 years of age, when children's emotional needs are both ignored and rejected.

Why do the vast majority of Ifaluk manage to avoid mental illness? The answer, according to Spiro, appears to be the sanctioned outlet that religion primarily affords. Aggression is displaced upon the malevolent ghost, the *alus*. Another important means of reducing hostility and anxiety and satisfying the Ifaluk's dependency needs, is the institution of the chieftainship. As the paramount Ifaluk chief put it,

The chiefs are like fathers here. Just as an empty canoe is tossed about by the waves and finally sinks, so, too, a society without chiefs is tossed about by conflict and strife and is destroyed. If a father asks his son not to behave badly, the latter may not obey him since he may not respect him highly. But all people obey the words of the chiefs, since they are feared and respected by all. The chiefs' duty is to see that the people behave well. The chiefs must constantly tell the people to be good, or else the society, like the canoe, would be destroyed.

In the United States quite a number of people felt the same way about Franklin Delano Roosevelt. When he died in 1945 it was for millions as if a protecting father had died. The importance of making a strong identification with a parental figure in the development and maintenance of mental health is today, I believe, abundantly clear.

The Ifaluk fear to lose the love of their chiefs and do everything in their power to maintain it. And this is the main incentive to conformity to the ethos of cooperation and kindness which the chiefs so prominently personify. The chief is a warm, loving, parental figure. The love and praise given by the chiefs provide the essential satisfaction and security of which the individual was deprived as a child.

Perhaps the Ifaluk has achieved an approximation to the Welfare State from which other societies could learn a thing or two. At any rate, the Ifaluk do afford an interesting case-history which may help us to understand better by what cultural devices mental illness could be kept to a mini-

mum in any society. The indications are that emotional stress, anxiety, and conflicting values must be as minimal as possible, but since such experiences are not wholly avoidable, that the culture provide institutionally sanctioned means for the expression of aggression and the reduction of anxiety, as well as support for the dependency needs of the individual. It is interesting to note here that in the western world mental illness is least frequent among the subscribers to that religion which makes a real attempt to satisfy these requirements, namely, the Catholic. This suspicion was corroborated by the findings of Hollingshead and Redlich on the population of New Haven, although they found that among the lowest class Catholics there were more frequently psychiatric patients than among either Jews or Protestants. Why this should have been so remains an interesting but unanswered question.

Fairly clearcut evidence of the relation between culture and mental illness is to be found in a culture which flourishes in our very midst, namely, that of the Hutterites. The Hutterites have a reputation for peace of mind, and many who have written on them have been lastingly impressed by this quality. Eaton and Weill and their co-workers, on first contact with them were struck by the generally prevailing atmosphere of relaxation, contentment, cooperativeness, and absence of manifested anxiety. Upon investigation, in the summer of 1951, it was found that out of a Hutterite population of 8,542 people, 199 or 1 out of every 43 living Hutterites were then mentally ill or had been previously.

The total number of schizophrenics was 9, manic-depressives 39, there were 53 with neuroses, 16 with psychophysiological disorders, and 6 with personality disorders.

Withdrawal in so well-knit a group as the Hutterites is difficult, and this Eaton and Weill suggest may explain the fewness of schizophrenics. On the other hand, depression appears to be an intensification of a culturally supported normative trend.

Among the Hutterites no cases have been known to occur of psychoses due to drugs, alcoholism, or syphilis. There were no psychopathic personalities. Murder, arson, violent physical assault, or sex-crimes were

quite unknown in this group. Only two persons showed moderately severe character disorders. Divorce, separation, or even family quarrels were rare. Violence, panic, and severe regression are uncommon, even among psychotics; suicide was extremely rare.

Eaton and Weill conclude that the facts justify the generalization that Hutterites tend to internalize their problems rather than project them into their relationships with other people. Under stress, they are much more likely to be anti-self than anti-social. The socialization process and communal indoctrination supports this normative behavior tendency. This emphasizes submission of the individual to community expectations, the principle of personal guilt and pacifism.

Such findings have led to the formulation of the hypothesis of specific cultural relevance with respect to the epidemiology of schizophrenia and manic depression, to wit, as we have already seen, schizophrenia is the disorder of social isolates and manic depression the disorder of the socially involved. At the same time the structure of Hutterite society does seem to show rather clearly the kind of cultural factors that are operative in relation to the production of individual and social disorganization or non-disorganization.

It is fairly evident today that all human beings at some time during their early development possess the potentialities for behaving in schizophrenic, manic, depressive, obsessive, or anxiety patterns. Whether an individual will respond to his behavioral environment, that is, his cultural environment, with one pattern of behavior or another will depend very much upon the pressures of that cultural environment, making all necessary allowances for genetic and constitutional factors. Some cultures produce more and more severe forms of these responses than others, and the cultural stresses that do so may vary in their nature in different cultures. In some cultures mental illness is institutionalized, by which is meant not that the individual is put into an institution as a sick man, but rather that he and his behavior are incorporated into the society as a normal part of it. The person whom we would regard as normal in our

society would be regarded as sick in such a culture. The diabolical, hostile, paranoid Dobuans of northwestern Melanesia make a virtue of treachery and ill-will, and would regard anyone who deviated from this pattern as utterly unfit to deal with the malignancies of this cutthroat world. Malignancy and hostility are therefore institutionalized as the ethos of Dobuan culture—it is a way of life.

Similarly, the Balinese, in a culture in which the food and material goods are adequate, war and crime at a minimum, the arts highly developed, the traumatizing experiences of childhood turn the Balinese into schizoid personalities. From about 5 or 6 months of age, and steadily becoming more definite as the child grows older, the mother continually tantalizes and teases the child. She stimulates him to show emotion, love or desire, jealousy or anger, and then turns away, as the child in rising passion ragingly and despairingly implores emotional response from her. The discouragement of interpersonal emotion is systematic. The child never attains a climax of emotional response, and the resulting withdrawal is seen in a lack of responsiveness which is established by the age of 3 or 4. The relationship to people remains distant, wary of the expression of too much feeling. When he is frightened, the Balinese falls into a soft sleep from which it is difficult to wake him. When he has to wait he may curl up into a fetal position and fall asleep. Within his own highly elaborate system of time and space he moves relaxedly and with grace; in an unknown situation he is unable to act at all. On tests, the Balinese respond like schizophrenics, yet they are fully functioning members of their community.

Responding to a question raised by Lauretta Bender, "How many schizophrenics can a society absorb and survive?" Margaret Mead says,

One might say that Bali had been able to absorb a much higher number of those who would be schizophrenic in other societies, until their special potentialities, seen now as one variant of human nature, had helped develop a social order that was self-perpetuating. To this all children born in Bali were exposed, they, in turn, absorbing, in posture and gesture and capacity to move within a highly protected,

symbolic system, something of the special gifts, the special vulnerabilities, the special sensitivities of the potentially schizophrenic, fitting in with the phrasing that "schizophrenia is not so much a disease as a way of life." In studying Balinese culture, the details of childhood experience may be seen as a way in which a culture perfectly adapted to the particular constitutional needs of schizoid individuals is communicated to all human children, involving far greater trauma for some than for others, subduing all to a state where they do not threaten the pattern, and developing an insatiable demand for symbolic rather than immediate satisfactions, turning the schizoid hunger for a meaningful pattern into an appetite for the practices of living arts (in F. Alexander, pp. 439-440).

The important thing to note here is that in Bali the schizoid habitus has become institutionalized and that it has given Balinese culture its essential character, in the arts, interpersonal relations, and in religion. This has been discussed by others elsewhere; here it must suffice to say that the arts, interpersonal relations, and religion are all greatly influenced by the prevailing psychosis—using that word to mean no more than "a state of mind"—and each of these cultural activities and institutions affords the individual abundant opportunities for the maintenance of his own self-homeostasis.

Thus, we begin to perceive how mental illness may, to a large extent condition the institutionalized forms of emotional expression such as religion, pageantry, painting, carving, puppet-making, music, the dance, drama, narrative, and the like. For in Bali it seems quite clear that these forms of emotional expression are designed to fit the requirements of the individual's emotional needs.

The effects of mental illness upon the structure and functioning of society is a matter which in our own time has assumed the dimensions of a world important problem. No less than the problem of the survival of mankind itself. The question is: How behaviorally deranged can a society get before it endangers its own survival and that of others? Before that question can be answered we must dispose of the doubt as to whether it is possible for a society to be behaviorally deranged, and

7.9.70

consider whether the phrase is only a figure of speech. I recall a brilliant book by an Englishwoman, Caroline E. Playne, *The Neuroses of the Nations*, published in 1925. It was 30 years before its time. I read it in 1925, and I also read the reviews. I was impressed by the book, but not by the reviews, which were largely scornful. How could a nation be neurotic? Neuroses applied to individuals, not to such complex entities as nations. This was the main criticism of what was otherwise conceded to be a well-written and interesting book. Only 8 years were to pass, or if you like 20, for Miss Playne's analysis of the German and the French neurosis to receive full corroboration from the tragic dénouement of events. But meanwhile Miss Playne's book and her examination of national neurosis has been forgotten. I should like briefly to quote her thesis in her own words. She writes :

The study on which we embark of the national group-minds of the two great continental representatives of Western civilization, France and Germany, is an examination of the nature of the limitation which in their case "held up" the generation who lived at the beginning of the twentieth century. And the contention is that the special limitation of human nature which hindered the progress of this generation was the failure of men's nervous systems to adjust themselves to the ever-increasing strain of life under highly stressed and complicated conditions of existence. Out of this failure of adjustment arose nervous excitement, nervous depression, general irritation, resulting in anger and passion. Primitive passions burst forth, accompanied by emotions of instinctive type. The effect of this upthrust of ancient and obsolete furies into the newer order was so turbulent, that . . . they swept the masses out of the path of reasonable advancement and plunged them into a series of group-neuroses.

Whatever one may think of Miss Playne's explanation of the dynamics involved, it took the spectacle of Nazi Germany to convince some observers, at least, that a whole nation could be mentally ill, for how otherwise would it be possible to account for the behavior of the Hitlers, Goerings, Goebbels', Himmlers, and Eichmanns, and countless others like them but by the history of the average German's behavior? Those who

had known many Germans and who ever gave the matter any thought, like those German exiles Heine and Nietzsche, were aware of what the Germans subsequently proved themselves capable. One does not have to read the memoirs of Nazi generals or concentration camp commandants to know that the cultural conditioning of a majority of the Germans was such as to make rigid, fearful, emotionally shallow and humanely arid, obsequious and obsequious creatures, who were never happier than when commanded or commanding. The parallel between German family structure and the structure of German political life is now something of a cliché of the psychiatry of peoples. Dr. Bertram Schaffner has discussed this subject in his aptly titled book *Father Land: A Study of Authoritarianism in the German Family*. The manner in which the adult German personality is formed within the German family in great part serves to explain that personality. The fear and respect, *Ehrfurcht*, inculcated for the father, *Pflicht* the obsessional sense of duty which seems to serve the German as a substitute for what is elsewhere known as a conscience, the absence of love, the subservience of women, the commanding position of the father, the word of the father as inflexible law, the unquestioning obedience expected of children and inferiors, the emphasis on work, the thoroughness and attention to detail, the fear of failure, the discipline and regulation, the enforced passivity of the child, the lack of freedom, and the like, would be enough in themselves to explain why the Germans are Germans.

No analysis can be attempted here of the historical conditions which caused German culture to develop in this way, but if there is one man who deserves a major share of the discredit that man is Martin Luther. It was not, however, one man, but many who were responsible for Germany's totalitarian development. Germany was and still is a nation of little Hindenburgs, Ludendorffs, and Hitlers. They are turned out as regularly and as invariably as a pattern made to a template. The patterning of the German personality has on two occasions already had the most devastating consequences for millions of human beings, and it may be predicted that it will again. Just as it may

be predicted that all American attempts to democratize the Germans will fail. The Americans helped the Japanese to achieve a democratic revolution that had already long been in the making. But can a nation of little Hitlers be taught democracy? I believe not. Democracy is something one learns in the home. It is not simply a political doctrine. Politics is life, and political attitudes are founded in the home. "Do you imagine" wrote Plato in *The Republic* "that constitutions grow at random 'from stone to stone,' and not from those characters of the men in cities which preponderate and draw the rest of the cities after them?" The characters of "the men in the cities" are determined by the agencies that shape them within the family. Democracy in Germany can come about, if at all, only by gradual evolution, and only after the German family has democratized itself. As things are today there is hardly a German who really understands the meaning of democracy.

The comparative psychiatry of cultures and of nations would be a fascinating topic to pursue further. It is a subject in the making. Each nation has its own psychosis, and some of them happen to be more dangerous than others. I hope I have said enough in this paper to suggest that it is a subject worthy of our closest attention.

I have thus far spoken of the influence of cultural factors upon the incidence of mental illness. I should now like to say something about the influence of the mental illness that prevails in any culture upon the condition of that culture. It should be clear that in a culture in which there are as many sick individuals as there are in Dobu that such a society must either ultimately destroy itself or change its character. Dobu is a remarkable example of what happens to a culture when virtually everyone in it is mentally unbalanced. Mental illness becomes the norm of behavior, and in a short time there remains no one in such a society who is able to perceive that such behavior is, in fact, socially maladaptive and destructive. The parallel to some western societies is rather deadly, and we in the western world have to ask ourselves, before it is too late, whether it may not be that at the present time we stand at the very edge of doom because mental illness has become endemic

among us and institutionalized as a way of life. We have to ask ourselves how mentally fit are those men in our culture who occupy high office and influence the lives of millions of others?

We have to consider whether motivations which move many men to acquire political power are not generated by something less than the desire to be of help to mankind, and we have, in addition, to consider whether the citizens who make it possible for such persons to realize their drive for power, are not perhaps as sick as those they elect.

Mental illness, it would seem, has not been uninfluential in the appearance of certain forms of art, architecture, and literature, not to mention many of the things that are said and done through the usual form of these arts.

A culture such as that of the United States, which not only permits but encourages the employment, for example, of newspaper columnists who are clearly mentally ill, in which such men grow to riches, fame, and even respect, evidently caters to the deepfelt needs of mentally sick individuals. This is further evident in the nature of the entertainments favored by the masses, in which murder, violence, rape, and sexuality form the staple article of diet, and in the plays having morbid and perverted themes for their plots. It would appear that it is no longer the blind who are leading the blind into the ditch, but the mentally ill who are leading the mentally ill, and contributing to the secularization of even greater numbers of mentally ill.

We stand much in need of a social psychiatry which will devote itself to the study of the causes and cure of the mental illnesses of cultures.

A VISIT TO THE ARGENTINE¹

JOSEPH WORTIS, M.D.²

An invitation to the Second Argentine Psychiatric Congress held in Mar del Plata November 2-6, 1960, provided a welcome opportunity to meet some of our South American colleagues, visit several institutions, and acquaint myself with some Argentine psychiatric activities.

In recent years there has been a very rapid increase of psychiatric interest and activity in the Argentine. Forty years ago there were probably no more than 50 Argentine psychiatrists, working mainly in hospitals; there are now over 600 physicians of various levels of training working more or less exclusively in psychiatry, most of them in private practice, including about 100 psychoanalysts. The first psychiatric congress initiated by cooperating psychiatric societies was held in 1956: the broadening professional interest, now involving psychologists and other auxiliary workers, led to a larger second conference in the beautiful sea port of Mar del Plata, south of Buenos Aires. There were about 500 participants, including nearly 300 psychiatrists. Several other South American countries were represented. The principal themes were mental health and work, clinical psychopharmacology, and the neuroses and psychoses of childhood; 100 papers were presented and round tables held. The entire proceedings will be published. In general the papers represented a sophisticated level of scientific interest, and there were frequent references to the social context of psychiatric disorders. There appeared to be a much greater willingness for different schools to meet together than is customary in our country. Very little experimental

work was presented, research design was negligent, and statistical refinement rare—all reflecting basically an inadequate support of psychiatric research. Many of the clinical psychopharmacological studies were directly sponsored by the drug companies, who helped support the Congress in other ways. The newer drugs are widely publicized and enjoy considerable vogue; they may be sold in the Argentine without medical prescription.

The fishing port of Mar del Plata is not only a resort for the *porteños* but has one of the biggest gambling casinos in the world, run by the provincial government. It has, moreover, a socialist mayor. Part of the income from the tourist trade goes into social services, and a modern cerebral palsy rehabilitation center, *Il Centro de Rehabilitacion para Niños Lisiados* (CERENIL), has recently been developed there under the enterprising leadership of Dr. Juan O. Tesone, an American-trained orthopedic surgeon who has not only brought new equipment and techniques to Mar del Plata, but has succeeded in mustering ample philanthropic aid from the local business interests. CERENIL has even been allocated a block of beach cabins whose lucrative rentals help support the service.

BACKGROUND

Nineteenth century Argentine society was still largely feudal, with a wealthy landed gentry that controlled huge holdings, an aristocratic ruling class and a large population of extremely poor peons or workers. Recent decades have seen the rise of a prosperous commercial and professional middle class who live in modern comfort in the large cities, with theaters, autos, opera and smart shops that rival the best of Europe's. But striking class differences still remain, and on the outskirts of Buenos Aires big areas of one-room hovels can be found, without water, electricity or sewage, where scores of thousands live in squalor, and where infant mortality in the summer months reaches terrible figures; con-

¹ I would like to thank my Argentine hosts for their unfailing friendly hospitality, and especially Drs. Locci and Barbagelata of the Mental Health Advisory Council, Dr. Torrence of the Statistics Division of the Health Ministry, Drs. Gregorio and Sylvia Bermann, Dr. Pichon Riviere, Dr. Recca and many others for their helpfulness in answering my many questions.

² From the Dept. of Psychiatry, State University of New York Downstate Medical College, and the Division of Pediatric Psychiatry, Jewish Hospital of Brooklyn.

ditions in the sparsely settled interior are said to be as bad or worse. According to the figures from the Ministry of Health, infant mortality in the country as a whole is 60 per 1000 (compared with 27 per 1000 in the U.S.A.) but is only 30 per 1000 in the populous cities—an average based on a very unequal rate in different sections. Infant mortality is especially high in the rural areas (in some districts as high as 200 per 1000) and over half of the children in these areas have intestinal infestation. Figures given to me at the Health Ministry indicate that expenditures for health services from all sources—public and private—amount to about 1200 pesos per person per year (\$15), but most of it comes from public funds. There are now 28,000 psychiatric beds in the country, but 48,000 are said to be needed (though some think it would be wiser to expand acute and preventive services). 50 to 65 pesos per person per day are paid for all services and maintenance for psychiatric cases in public hospitals, but officials told me they need at least 100 pesos per day as a bare minimum. In the larger public general hospitals in Buenos Aires the present costs are 400 pesos per day per patient. Other welfare services related to psychiatric needs are similarly backward, so that social factors not only create excessive psychiatric morbidity, but prevent effective treatment and rehabilitation. Recent inflationary trends have aggravated the whole problem.

The population of the country has increased rapidly from less than 5,000,000 in 1900 to over 20,000,000 at present. Much of its immigration is thus relatively recent. Argentina is the most European of the Latin American countries, with relatively little Indian and practically no Negro population. In spite of some very poor areas, it is economically the most advanced country in South America. It has always been strongly bound by economic ties to European and more recently American interests, and its upper classes were typically educated in foreign or foreign-language schools. At the beginning of this century its neurology and psychiatry were mainly influenced by the French; after World War I German and to some extent English influences appeared, but for the past 2 or 3 decades

its psychiatric orientation has been increasingly American. In the past few years a small but influential Pavlovian group has been following the Russian literature. Most of the books on display at the Congress were translations of American authors. The past period has also seen a definite separation of psychiatry from neurology, a huge increase in the private practice of psychiatry, and an active development of psychoanalysis.

Argentina is proud of its own psychiatric traditions. Diego Alcorta (1807-42), like our Benjamin Rush, was inspired by French influences and was interested in both physical and social causes of psychic disorder. José María Ramos Mejía (1850-1914), Domingo Cabred, (Professor at Buenos Aires until 1916), José Ingenieros (1877-1925), Christofredo Jakob (1806-1956), are all illustrious names. Angel Garma who migrated from Spain after the Civil War, founded the influential Argentine psychoanalytic movement, and is still active. Eduardo E. Krapf, formerly professor at Buenos Aires, now heads the Mental Health Section of the World Health Organization. Dr. Gregorio Bermann, another early psychoanalyst, has since defected to the anti psychoanalytic camp, apparently without damage to his high standing in the profession. The Argentine Psychoanalytic Association now has about 100 members, half of whom are following what could be called a neo-Freudian orientation under the leadership of Dr. Enrique J. Pichon Riviere, who was President of the current Psychiatric Congress. This latter group has its own teaching center, the *Primera Escuela Privada de Psiquiatría*, affiliated with the Argentine Institute of Social Studies.

HOSPITAL NACIONAL NEUROPSIQUIATRICO

• Following the conference, I spent a week visiting various psychiatric facilities around the city. When I said I wanted to see their worst as well as their best I was advised to visit the federal *Hospital Neuropsiquiátrico* in the suburbs. The hospital consists of a neglected group of stucco and concrete buildings on grounds that are no more than heaps of stone and sandy rubble. It houses 3,500 patients on a budget of 50 pesos per patient (42c) a day, without a single full

time trained psychiatrist, very few trained nurses, not a single social worker, and with 6 attendants per 24 hours for each unit of 124 patients. About 82 visiting physicians work about 18 hours a week, for which they are paid 4000 to 5000 pesos a month. The Director, Dr. Omar J. Ipar, gives the hospital 6 hours a day. Many patients help care for other patients, and the inmates comprise 80% of the working staffs in kitchen and laundry. Psychotic patients roam the open grounds unattended. An average of 2 patients a day wander off or escape; 90% are returned. There are 1200 admissions or readmissions (75%) a year. Of every 100 new cases admitted 50 remain in the hospital while 50 die or are discharged. The illicit smuggling of alcohol into the hospital grounds is a constant problem. Tuberculosis was formerly rampant, but is now controlled with antibiotics. There are 250 deaths including 7 suicides a year. General conditions seemed deplorable, though some sections of the hospital were being renovated. Aside from the work the patients do to maintain themselves, there was little planned occupational activity, and I saw many patients lolling on their beds in mid day, or gazing vacantly at the walls. In the event of discharge, there is usually no follow-up.

A program for the training of 12 part time residents began four years ago and was said to be going well. Regular staff meetings are held, and the hospital has just resumed its annual neuropsychiatric bulletin and journal. Fortunately an association with a specialty hospital such as this is still regarded as a prerequisite for professional standing in private practice. Though the caliber of the doctors I met seemed to be good, their opportunities for useful work under these conditions were discouragingly limited. I saw 2 busy and well equipped pathology sections however, and some work in chemistry and pharmacology was being done.

POLICLINICO DE AVELLANEDA

A visit to the small psychiatric services of Dr. Sylvia Bermann in a general hospital was a pleasant experience. Staffed by a few dedicated psychiatrists, mostly women, it was providing excellent services to children

and adults in an atmosphere of warmth and serious scientific interest. A small 10-bed inpatient service for the active treatment of acute psychoses was a welcome new asset to the hospital, and relations to other hospital departments were excellent. Dr. Bermann was being paid 4000 pesos a month for directing this service, though it was her major activity, and some of her staff physicians got no pay at all.

CHILD PSYCHIATRIC CLINIC, HOSPITAL ESCUELA SAN MARTIN

Dr. Telma Reca de Acosta, a quiet and charming woman with some American experience, heads the newly developed university children's psychiatric clinic at the *Hospital Escuela San Martin*, housed in an ample though sparsely furnished wing of the newly constructed university hospital. Though there are 2 other small children's psychiatric services in this city of 6,000,000, hers is the best known and is trying bravely to meet the rapidly growing demand for services. It is staffed by 5 part time psychiatrists who are paid the equivalent of \$60 a month, a few psychologists, and some non-professional assistants, but so far by no social worker. The clinic handles 25 new cases a week; few children can be seen more than once, and most of the follow-up work is done with the mothers in groups set up mainly according to the age of the child. There is no waiting list; in this way maximal use is made of the scarce professional personnel. Two-thirds of the referrals involve reactive behavior disorders or neuroses, about 10% to 15% are problems of mental defects, and there is a small percentage of psychoses. Except for some of the retarded children, there is no special public school classes for these disturbed children, and no available residential facilities for childhood schizophrenia, a group for whom Dr. Reca is attempting some special therapeutic help. Several physicians attend the clinic for training, since residency training in the specialties is still not established in the Argentine. Although present operations are relatively modest in scope, the establishment of this new clinic is significant, and will undoubtedly lead to bigger developments.

POLICLINICO DE LANUS

This university service of psychopathology and neurology under Dr. Mauricio Goldenberg is generally regarded as the best psychiatric clinic in the country. It is housed in a busy public hospital comparable to Bellevue in New York City, and has both an outpatient, and an inpatient service of 32 beds—practically all used for psychiatric cases. It has 35 staff physicians, most of whom give half their time to the clinic, though only 5 are paid—\$50 a month, with \$75 a month for the chief. Seven of the psychiatrists specialize in group therapy. There are 7 well trained psychologists, plus a number of psychological trainees. The clinic boasts one full time social worker and hopes soon to have a number of psychiatric residents in training; it handles about 40 appointments a day and takes on about 35 new patients a week. Its psychiatric case material consists largely of neuroses, early psychoses—mainly depressions—and alcoholism. I was told that after a few visits most patients tend to drop out. Group therapy is a special interest of the clinic, and some of the patients are treated on a day hospital basis. It conducts considerable research, most of it involving the newer drugs, and all of it supported by the drug companies. Its orientation is Pavlovian (misnamed “reflexological”) and it is active in developing a school of psychotherapy with an experimental basis, largely under the leadership of Dr. José A. Itzigsohn, a Russian-born psychiatrist and translator of Pavlov.

At this clinic I met with a large group of medical students, who wished to ask questions, first about psychiatry, and then about the U. S. A. Half of them said they would like to train in the States because full time training opportunities have only begun to be developed in their country. As a group they seemed to be well-read and surprisingly well informed on broad social issues, a characteristic, I was told, of most South American students. They were alert to the pressing need for medical progress and reform, seemed especially interested in knowing of different psychiatric schools of thought in America, and carefully noted the names of all the authors I mentioned.

A PSYCHOANALYTIC GROUP

I spent an interesting evening with some 20 young analysts associated with Dr. Pichon Rivière. I was encouraged to give my views and join in discussion of a variety of psychiatric topics, all duly tape-recorded. Discussion continued until well past midnight, which is said to be not unusual in Buenos Aires. Major interest was focused on psychotherapy but I was most favorably impressed by the breadth of interest of this group and their receptivity to new ideas. Many unfortunately were losing contact with hospital work because it was demanding and unremunerative. I think it would be a pity if means were not found to bring their interests and talents to medical settings and to broader services.

PUBLIC HEALTH AND PSYCHIATRY

I had an opportunity to meet with Dr. José Luis Locci of Rosario, the chief psychiatric advisor to the National Ministry of Health, and Dr. Ricardo R. Barbagelata, a teacher of psychology in one of the provincial universities, who is also an adviser to the National Committee of Mental Health. They told me that the present national psychiatric budget amounts to 637,000,000 pesos a year (about \$8,000,000) exclusive of construction. This is used almost entirely for the care of the 22,000 psychiatric cases in national hospitals (there are also 6,000 in provincial or private hospitals), an additional 4,000,000 pesos a year are allocated for research, and a similar amount of preventive work. They frankly emphasized the very serious shortcomings of their present psychiatric services and felt that the Government must take quick action to satisfy even the minimal needs of the population; many additional beds were needed for psychiatric cases and they thought that the budgetary allotment for each bed should be substantially increased. Except for one small university service in La Plata and an institution for the feeble-minded the country had no residential psychiatric facilities for children. There is not a single full time head of a psychiatric service in all the Argentine. There is official appreciation of the need for such positions, and for the expansion of psychiatric services in general hospitals, all within a broad

framework of augmented medical services for the whole nation, similar to the comprehensive health services in the neighboring state of Chile. The day hospital was favorably regarded.

CONCLUSIONS

Argentina has its fair share of talented and public spirited psychiatrists, but their professional development and usefulness are hampered by inadequate support and facilities. The opinion was frequently expressed, even by Government officials, that general planning for medical services on a national level is long overdue, and will have to be initiated. Even the 1200 pesos per year per capita that are now being spent by the public could yield far better health services, including psychiatric services, if expended in some planned and rational way. Until that is done, there seems to be little prospect of providing adequate psychiatric care to meet the needs of the Argentine population. Meanwhile it is to be hoped that some of the most urgent and immediate needs will be satisfied.

A question I often asked was how we in the U. S. A. could be helpful. Many younger physicians expressed the wish to spend a period of training in the U. S. A., but it is my impression that in the past many or most of the American-trained physicians have returned to give their major

interest to private practice and have neglected hospital work. "How else could we earn a livelihood?" they ask. It seems to me American training resources could be used much more effectively if our responsible agencies negotiated with Argentine agencies to exchange personnel, or perhaps teams of personnel, with some assurance that these would help satisfy some of the broader psychiatric needs of that country. Now especially, when there is emerging in the Argentine a new interest in the development of psychiatric services in general hospitals, perhaps ways could be found to train some of their younger men to prepare for full time career positions in general hospitals, in research or in psychiatric public health work. I think brief sojourns of visiting teams from our country would not only be well received and would help to train many young psychiatrists, but would provide useful opportunities for some of our psychiatrists to get the stimulus of new contacts, problems and ideas, and to cultivate an interest in the growing psychiatric work of our South American neighbors. Joint conferences or group training seminars could also provide very fruitful results at relatively little cost. I am sure that programs of this type would help to revive those good neighborly feelings which have not flourished in recent years.

THE TREATMENT PROGNOSIS FOR FUNCTIONAL PSYCHOSES IN GREAT BRITAIN

WILLIAM SARGANT, M.B., F.R.C.P., D.P.M.¹

Because modern methods of treatment of both schizophrenia and depression are now getting patients better much more quickly and with so much less chronicity, the Minister of Health has announced recently that within the next 15 years it should be possible to close no fewer than half the total beds in British mental hospitals, as well as treating most of the acute recoverable patients in much smaller psychiatric units attached to general hospitals.

How has this revolution in the treatment of the functional psychoses in Great Britain been achieved and why? Certainly, when the writer first entered psychiatry in 1934, such future top-level planning would have been quite inconceivable, and the position then was a very different one, even as regards the predicted treatment outcome of the most favourable cases of early schizophrenia and depression. However, it is now very often forgotten that in those days the only specialised methods of treatment available for such cases were the methods of Freud and Jung and some of the simpler forms of psychotherapy, while the only physical treatments were drugs such as the bromides and paraldehyde. In England, simply because there were then so few other treatments apart from the psychotherapeutic ones, and because a strong Freudian movement had existed in England since the end of World War I, psychotherapy and psychoanalysis were certainly tried in the treatment of selected functional psychoses as well as in the neuroses. However, their failure to cope with but a few of the enormous numbers of the mentally ill demanding urgent help at that time is now a matter of psychiatric history. And we also remember the truly deplorable state of British mental hospitals when psychotherapeutic and social methods of treatment were the only ones available to help so many thou-

sands of the mentally ill demanding urgent relief.

Before World War II, however, we saw a new treatment break-through with the advent of several fresh physical methods emanating from European clinics. The value of insulin coma, convulsion therapy, and lobotomy in the functional psychoses were all suddenly discovered and later widely used. World War II also provided British psychiatry with a further convincing demonstration of the effectiveness of physical methods of treatment, which by then included "front line" sedation, drug abreaction, continuous sleep, various forms of insulin therapy, electroshock treatment, and the like, in the handling of the enormous numbers of military and civilian psychiatric casualties, as compared to World War I when again only such methods as hypnosis and psychotherapy were usually available. As a consequence, millions of dollars in pensions have been saved the British Government in part at least because so much less chronicity has resulted from the treatment methods used in World War II compared to those of World War I.

These new treatment developments were then fortunately followed up with a return to peacetime psychiatry in Britain, and the resulting revolution is now becoming very obvious both as regards the prognosis and the duration of illness in patients with functional psychoses, which still fill the majority of mental hospital beds in every country in the world. But to obtain the full benefits from the use of all the newer physical methods of treatment now available, it is necessary to use them with courage, selectivity, skill, and a determination not to go on trying to pretend, as often happens in the U. S. A., that they are merely a second-best form of treatment, whose main value is to get a patient ready for the analytic couch or for other forms of specialised psychotherapy. This is especially the case at the present time when there are, in fact, so few psychotherapists available to help the

¹ Physician in charge of the dept. of Psychological Medicine, St. Thomas' Hospital, London, England.

thousands of patients in mental hospitals even in such comparatively wealthy countries as U. S. A. and Great Britain. In fact, the treatment revolution that has happened in England, and which may allow the closing of such tremendous numbers of its mental hospital beds, has all occurred with very little specialised psychotherapy proving necessary at all, or even being available if it were.

How greatly improved the treatment prognosis has become for the functional psychoses in Britain is also shown by the fact that the doors of most of the wards of mental hospitals can now be left wide open, and the majority of patients in them treated on a purely voluntary basis. But in many other countries and, unfortunately, in a few conservative or backward British mental hospitals, this is still not possible, simply because the uses of the newer methods of physical treatment have not been active enough, and there are far too many agitated and mentally tortured patients only awaiting opportunity to rush out and kill themselves because of the severity of their continued suffering. To have opened the doors of British mental hospitals, and of its general hospital psychiatric treatment units, when only psychotherapy and social treatments were provided for patients would have resulted in disaster, and would have led to a rapid discrediting of the whole system.

In fact, to get to our present favourable treatment position in Britain, around 15,000 lobotomies (mostly modified operations compared to the standard Freeman and Watt's technique) have already had to be done on our more chronically agitated and mentally distressed patients; and the tranquillizers have certainly proved to be no satisfactory substitute for modified lobotomies in so many of them. An official government enquiry has also just established that over 45% of over 10,000 lobotomised chronic patients in British mental hospitals have been able to be discharged, many of them also returning to work, while the relapse rate was much lower than expected. Since the introduction of the phenothiazines, this too has helped to stabilise still further some of the improvements seen after operations;

it has also helped to make lobotomy unnecessary in others.

Insulin coma, too, has had to be used since the war in practically all the mental hospitals in Britain to get these results, rather than simply giving long courses of EST even to recent, acute, and still recoverable schizophrenic patients. Now, fortunately, it seems that EST and the phenothiazines, when used together, are generally providing a better and more speedy remission in more patients than when insulin coma and EST were used. But additional modified insulin régimes are still having to be employed to restore body weight to normal in schizophrenic patients before their discharge from mental hospitals, and under the National Health Service, maintenance treatment with the phenothiazines is also provided following discharge, and indefinitely where necessary, to help to prevent relapse.

With the advent of the phenothiazines, it has also been shown that many acute schizophrenias can be treated in general hospital psychiatric wards with open doors, or even as outpatients in general hospital psychiatric units and day hospitals, provided that convulsion therapy, modified insulin, and the new tranquillizing drugs are all made available, and on an outpatient basis where necessary. The treatment time for an acute schizophrenic illness is consequently often being reduced to 8 weeks or less, compared with the months and years that it used to take to induce remissions in much smaller numbers of such patients, when psychotherapeutic and social methods were our only real treatments prior to World War II.

It has been the same in the treatment of moderate and severe depressions in Britain. The widespread use of outpatient EST, now often provided by general hospital psychiatric units under the National Health Service, the additional provision of modified insulin treatment where necessary, the selective use of the amphetamines, and the wide range of long- and short-acting barbiturates which are now available, and, when all else has failed, a final selective use of the newer modified forms of lobotomy, have made the long and agonizing depressive illnesses of the past a very rare occurrence. Furthermore, the newly increasing range of antidepressant drugs, which are bringing

so many of the anxiety states and the neuroses with depressive features within the range of simple chemotherapy, has made the treatment of the whole group of depressive illnesses quite unrecognizable compared to that prevailing only 25 years ago. Then it might take depressed patients months or years to get better, and so many of them eventually killed themselves or died of agitated exhaustion in mental hospitals, despite all the forms of therapy used to try to help them.

The writing has certainly appeared on the treatment wall in recent years for those prepared to read it. But in some countries like the U. S. A., the millions of dollars provided by the government and other wealthy foundations for psychiatric treatment research are still being concentrated too much on the "dynamic" psychopathologies and on psychotherapeutic approaches, which have proved so disappointing up to now in getting patients out of mental hospitals. This is difficult to understand since psychotherapeutic and analytic treatment has in fact as yet to prove its real worth even in the treatment of the more severe forms of neurosis. Meanwhile only a comparative pittance is being provided in various countries for research into the many possible physical and physiological treatments in psychiatry which have really brought about the recent therapeutic revolution wherever they have been fully and courageously used. Also, while the possibilities of these new methods of treatment of the mentally ill are still underdeveloped and comparatively in their infancy, it is likely that the possibilities of the psychotherapeutic and social treatments of both the psychoses and the neuroses have

already been fairly fully explored during the past 50 years. And, *when used alone*, it is almost certain that they will be found just as unable to get more than small numbers of patients out of mental hospitals in the future as they have been in the past.

Some people even in Britain have, however, tried to deceive themselves into believing that the present improvement in treatment prognosis has been due largely to the better social, individual and group psychotherapeutic treatment facilities that have also sometimes been available in recent years, along with the recent opening of the doors of our mental hospitals. Certainly all such procedures do help to supplement each other ; but one can quite safely predict that we would only have to give up the use of all the newer physical treatments for a very few months in Great Britain, and most of the doors of our mental hospitals and the wards of psychiatric units in general hospitals would have to be closed again, and the bars would go back on the windows because of the numbers in them trying to kill themselves during much more prolonged and intolerable illnesses. Conditions would speedily revert to those seen when social and psychotherapeutic methods are given too much prominence and prestige at the expense of the full use of the newer physical treatments. It is only these latter that have made possible the revolution that has occurred in the prognosis for the recoverable psychoses in Great Britain today ; and they have also helped to give less effective social and psychotherapeutic methods an added value which they could never have hoped to have obtained in their own right.

MENTAL DISEASE OR DEFECT EXCLUDING RESPONSIBILITY¹

A PSYCHIATRIC VIEW OF THE AMERICAN LAW INSTITUTE : MODEL PENAL CODE PROPOSAL

LAWRENCE ZELIC FREEDMAN, M.D.,² MANFRED GUTTMACHER, M.D., AND
WINFRED OVERHOLSER, M.D.

It is a truism that in any decision making process the freer the flow of relevant information the greater the chances that the decision will be rational and just. Any impediment to pertinent communication increases the probability that irrational or, in the court of law, unjust decisions will be made. The clinical insights of psychiatry can accurately reflect the state of its knowledge and be efficiently utilized by courts only when the procedures for testifying do not suppress or distort the information. The fewer the restrictions imposed on the psychiatrist testifying in court, the greater the resources upon which the courts can draw.

Decisions concerning the legal criteria for excluding responsibility obviously belong to other members of this Committee. The considerations which we are presenting arise from and are restricted to our area of training, competency and primary interest—mental disease and mental defect. Only so far as the proposal attempts to incorporate psychiatric disease need the Committee grant our advice any more weight than that of other interested laymen. However, so far as it does, we think it reasonable to hold that the unanimous opinion of the three psychiatric members of the Advisory Committee ought to be weighed as representative of the thinking of many of our colleagues in psychiatry upon whom the success of any formula depends.

There is now a body of experience based on the history of the MacNaughton formula which may guide us to avoid a repetition of difficulties arising from earlier efforts. For example, a serious impediment to meaning-

ful communication between psychiatrists and lawyers in the MacNaughton formula is the psychiatrists' mistaken assumption that MacNaughton makes an attempt to define insanity which they consider in error. Lawyers see it as a statement of the conditions under which an accused person might be exculpated from guilt and from being stigmatized as a criminal.

The traditional reluctance of psychiatrists to testify in courts under the MacNaughton formula arises in large part from the frustration of language which the law requires of them. Many lawyers have failed to realize that freedom of psychiatric testifying is not identical with extension of psychiatric concepts in the procedures and decisions of the courts. Courts can only benefit from having the greatest possible clarity of exposition of psychiatric testimony, no matter what standards it sets for responsibility.

Section Four of the Model Penal Code of the American Law Institute,³ devoted to Responsibility, has a dual function: It sets up the criteria by which, according to law, mental disease or defect may exclude responsibility. Responsibility is not a qualitative or quantitative intrinsic attribute of a person; it is, in this context, a legal judgment. Since, however, "the deed does not make the criminal unless the mind is criminal," the state of mind must be ascertained and a pathological state of mind is a psychiatric problem. However, the gauge for determining legal exculpa-

³ The proposed American Law Institute formula: Section 4.

1. A person is not responsible for criminal conduct if at the time of such conduct as a result of mental disease or defect he lacks substantial capacity either to appreciate the criminality of his conduct or to conform his conduct to the requirements of law.

2. The terms 'mental disease or defect' do not include an abnormality manifested only by repeated criminal or otherwise anti-social conduct.

¹ This is the minority report of the psychiatric members of the Advisory Committee to the American Law Institute preparing a Model Penal Code.

The preparation of this paper was supported by the Foundations Fund for Research in Psychiatry.

² Center for Advanced Study in Behavioral Sciences, 202 Junipero Serra Blvd., Stanford, Calif.

tion is not suitable for the differential diagnosis of psychiatric disability.

So, Section Four also sets up standards, it guides, and it limits the communications of the psychiatrists concerning mental disease and defect to the judge and the jury who are to make the legal decision. It is this second and to some extent competing function which concerns us. Confusion arises from this paradoxical effort to combine in one formula: 1. The criteria by which the courts will hold a man not legally responsible (*i.e.*, punishable) and 2. The conditions for the exposition of the psychiatrist's knowledge.

The question clearly should be: How may the courts optimally elicit testimony from the psychiatrist concerning psychopathology so that its own legal question concerning responsibility may be answered with maximum information at its disposal?

The two major formulae, competing to supplant MacNaughton, are the proposed American Law Institute prescription and the Durham Decision.⁴ In our view both are refreshing and encouraging advances over MacNaughton and reveal significant agreement. The similarities between them might be summarized as follows: 1. Each is intended to free from responsibility a man who has committed an illegal act which is the result of, or the product of, mental disease or defect; 2. Each includes mental pathology—illness, disease or defect; 3. Each rejects exclusively cognitive or intellectual approach; 4. Neither formula, presumably, is primarily concerned to define mental illness but rather to indicate what degree of severity of mental illness protects an individual against the punitive and stigmatizing impact of criminal law; 5. Each incorporates the concept of causality, with the words "product of" and "as the result of." Both "product" and "result" refer to the cause. Cause is the circumstance, condition, event, which necessarily brings about or contributes to a result.

Within this framework we state our reservations concerning the American Law Institute formula. We hold that the subtlety,

complexity and obscurity of its psychological entities and its actual intrusion into the field of psychiatric diagnosis unnecessarily limit the contributions of psychiatry, present and potential, and needlessly restrict the medical and psychological resources upon which the court may draw. The legal requirements concerning appreciation of criminality and conformance of conduct and the negative definition that repeated criminal or otherwise antisocial conduct is not mental disease effect a gratuitous entrance into medical and scientific arenas which is unnecessary and may be harmful to the law's purposes.

Specifically, "substantial" and "capacity" are psychologically vague, ambiguous, unclear and complex quantitative concepts. More important, "to appreciate the criminality" is an involved cognitive phrase at least as likely to lead to confusion as "knowledge of right and wrong." Further, since criminality is an illegal act *with an accompanying mental state*, is there not a logical inconsistency or tautology here? For if the offender cannot "appreciate the criminality," then his act is not criminal, and if it is criminal then he must have "appreciated" it.

"To conform his conduct to the requirements of law" is an inverse restatement of irresistible impulse which has proven to be an almost unusable defense. To lack "substantial capacity to conform his conduct to the requirements of law" is to have an irresistible impulse.

The terms "mental disease and defect" specifically exclude "an abnormality manifested only by repeated criminal or other antisocial conduct." To refer to mental disease and then to limit its meaning is to rob the court of the worth of the psychiatrist's expertness precisely to the degree that it limits his ability to transmit clinical information. It predisposes to failure in communication. The phrase "mental disease or defect" should serve as a focus for the communication and description of the combined behavior, feeling, ideas, of a person so as to inform judge or jury.

If the courts wish to determine whether mental disease or defect exists, then the law must use not only the semantics but the substance of psychiatry. It cannot, for example, meaningfully adopt psychiatric

⁴ Durham Decision: An accused is not criminally responsible if his unlawful act was the product of mental disease or mental defect. [94 U. S. App. D. C. 228, 214F2d862 (1954)]

words, and then appropriate to itself the right to establish psychiatric diagnosis criteria even by exclusion. It legally excludes forms of behavior which may themselves be symptomatic of pathology, for antisocial behavior may *be* the manifestation of illness. Repeated illegal or antisocial conduct is a manifestation of a personality, and this personality may be a sick one. There is a quality of behavior referred to as alloplastic, most commonly found in the psychopathic personality in which the symptom of psychopathology consists in the *acting out*. The manifestation of a man's abnormality may consist precisely in his repeated or otherwise antisocial conduct. To exclude such conduct from "mental illness" is to make a psychiatric judgment eliminating behavioral or conduct disorders.

Apparently there is no insistence on legal formulae in diagnosing physical diseases, so why in this case? If the physician were similarly forbidden to use one outstanding symptom as criterion for physical illness, the absurdity of such an approach would become apparent, or if he were limited to two tests it would be considered unscientific.

If the intent is to exclude the so-called psychopathic personality from irresponsibility, it is hard to see how it can succeed in this way. If the Committee does not want to excuse as psychiatrically ill individuals the so-called psychopathic or sociopathic personality, this formula will not serve that purpose, for its use depends upon the testimony of psychiatrists; those who consider

psychopathic or sociopathic personality a mental disease or defect will so testify and those who do not will not.

In summary, essentially the Model Penal Code formula has added to the cognitive criteria volitional criteria. It has eliminated behavioral criteria except when they are combined with other phenomena.

The Durham Decision permits free communication of psychiatric information and the American Law Institute creates road blocks to such transmission. The Durham formula puts no limitations on psychiatric testimony except those which are implicit in the present state of the discipline. The American Law Institute formula requires psychiatric judgments as to substantial capacity, demands essentially cognitive criteria concerning capacity to control, and insists upon including legal criteria in the old tradition by attempting to eliminate the psychopathic personality.

Neither the Model Penal Code nor the Durham formula resolves the problems of psychiatry; no legal formula can. Psychiatry is an incomplete scientific and medical specialty. Indeed all medicine and science are developing and hence are incomplete. This is reason to encourage its contribution rather than to emphasize its limitations in the courts.

For these reasons, we recommend the adoption of the historic practice of the New Hampshire Court as recently reformulated in the case of *Monte Durham*.

THE PROGNOSIS IN UNPSYCHOANALYSED RECOVERY FROM NEUROSIS

JOSEPH WOLPE, M.D.¹

Psychoanalysts have contended that, in general, recovery from neurotic disturbance is not likely to be stable and enduring unless the patient has undergone psychoanalytic therapy. For example, Fenichel(5) asserts that "there is no doubt that psychoanalysis, as the only radical method is the best method available for the treatment of neuroses"; and since other methods leave the neurotic roots untouched, their effects are "unreliable." In like vein, Hendrick(10) attributes the results of other methods of therapy either to suggestion or to positive transference and regards them as symptomatic and temporary, and when due to transference, "dependent upon maintenance of rapport with the therapist." If, and only if, such statements can be substantiated can psychoanalytic therapy, with its great expenditure of time and money, be regarded as the treatment of choice for patients suffering from neurotic symptoms.

Yet, apparently, these confident assertions have not been supported by anything other than anecdotal testimony. To establish the position, statistical evidence is essential. It is not sufficient that here and there a nonanalytically treated case relapses; it is necessary to demonstrate that neurotic reactions, overcome without the use of analytic methods, will *usually, or at least often*, recur or be replaced by other neurotic reactions.

The psychiatric literature contains a good deal of data relevant to this issue. Such data, without exception, contradict the belief that recrudescence is common when neurotic reactions have been overcome without psychoanalysis. In a follow-up study of apparently cured or much improved neurotic patients who had been treated at New York Hospital by methods that included some interpretative psychotherapy but not psychoanalysis, Hamilton and Wall(9) found that 51 of 53 male patients had

maintained their improvement for 4 years or more; and Hamilton, Varney and Wall (8) made the same observation regarding 66 of 67 females followed up 5 to 15 years. In a survey of 500 miscellaneous cases from the Tavistock Clinic, Luff and Garrod(13) noted that discharged as "much improved" were 72 cases of anxiety state, 13 of hysteria, 9 obsessional, and 5 cases of reactive depression, after treatment that was usually "comparatively short," consisting of re-education and explanation of symptoms. Three years later, the numbers "much improved" in each of these diagnostic groups had actually risen slightly. In line with these observations, I have reported(21) that relapse was noted after 2-7 years in only one of 45 neurotic patients who had been treated by methods based on learning principles. Similarly, Stevenson(17) found no evidence of relapse in any of 12 patients rigorously followed for periods ranging from 1-5 years. Adding these figures together, we find 4 relapses out of a total of 249 patients, or less than 2%.²

PRACTICAL IMPLICATIONS

Most patients come for treatment of neurotic illness because they desire to be relieved of the suffering and attendant disabilities. The therapist's first task is to decide what form of treatment to advise. The belief is widespread that psychoanalysis is the only "causal" treatment and should therefore, as a general rule, be recommended when available to patients who can afford it. Insofar as this belief depends upon the presumption that the results of nonanalytic treatment are impermanent or provisional, it is undermined by the evidence presented above, that heterogeneous methods of psychotherapy achieve remissions of suffering whose reliability can scarcely be bettered; and it is not impossible that

²It is consonant with this that Wallace and White(18) have recently presented data confirming the casual observation that neurotic patients often recover lastingly without having had any formal therapy.

¹From the Department of Neurology and Psychiatry, University of Virginia School of Medicine, Charlottesville, Va.

measured by this yardstick psychoanalytic therapy might actually prove to be inferior! It is relevant that Freud(6) describes two cases (and refers to "a large number of similar ones") in which symptoms recurred several years after the end of successful analysis. (To say, as some analysts may, that the relapses show that these analyses were not *really* successful or were incomplete, merely begs the question.)

However, even though considerations of durability of effects do not establish a preferential position for analytic therapy, its prodigal expenditure of time and treasure might still be justified if the *percentage* of patients to obtain benefit were substantially greater than with other methods. But comparison(3) of various reported series of patients has not shown that psychoanalysis produces marked amelioration of neurotic reactions any more frequently than various traditional therapies do. Moreover, recently developed methods of therapy based on principles of learning(20, 21, 4) appear to be producing a very significantly higher proportion of recoveries than either psychoanalysis or the traditional therapies.

In the light of these facts, what is to be said of the contention that nonanalytic therapies merely treat symptoms and "do not get to the root?" This contention is true only if the psychoanalytic theory of neurosis holds good—an assumption which we shall dispute in the final section of this paper. It is, of course, possible "merely" to treat symptoms—for example, by giving the patient a sedative. But if the truth should be that neuroses are persistent unadaptive habits of reaction and that symptoms are simply the evoked reactions, then to remove the habit will remove the symptom lastingly, by removing its basis. In short, anxiety that is a conditioned response can be permanently removed by deconditioning; which would not be expected of anxiety that is part of a "defense mechanism."

It seems reasonable on the available evidence to conclude that for patients whose sole requirement of treatment is *to be lastingly freed of neurotic symptoms*, there are no grounds for regarding psychoanalytic therapy as the treatment of choice: in fact, its inordinate length places it low in recommendability.

Of course, analysts claim effects for their therapy that go beyond symptom removal. It is credited with a unique capacity to bring about changes characterized by such terms as "maturation" or "balanced integration." When these terms are adequately defined, it will become possible to examine whether or not psychoanalysis is a superior method of bringing about the changes specified. In any event, such changes should surely be sought after only in those who desire them: they should not be represented as prerequisites to lasting recovery from neurotic symptoms.

THEORETICAL IMPLICATIONS

(a) *Implications for Freudian theory.* The erroneousness of the psychoanalytic prediction with regard to patients who recover without psychoanalysis has theoretical implications that are at least as important as the practical ones. Some of the most basic tenets of psychoanalytic theory are placed in grave doubt by the failure of this particular prediction. As will be seen, this applies as much to recent modifications of the theory as it does to Freud's own formulations.

In general terms, Freud's theory of neurosis is that neurotic symptoms are outward manifestations of emotional forces that have been repressed, and constitute compromises between partial discharges of these forces and various "defensive forces" that resist discharge. In a summary of his position in 1922, Freud wrote(6):

The neuroses are the expression of conflicts between the ego and such of the sexual impulses as seem to the ego incompatible with its integrity or with its ethical standards. Since these impulses are not *ego-syntonic*, the ego has *repressed* them . . . But the achievement of repression fails particularly easily in the case of the sexual instinct. Their dammed-up libido finds other ways out from the unconscious . . . What results is a *symptom* . . . Symptoms are in the nature of compromise-formations between the repressed sexual instincts and the repressive ego instincts . . .

The therapeutic results of psychoanalysis were to be achieved through making the repressed impulses conscious, overcoming the "resistances" that arose to thwart this.

Freud claimed to have shown that "... the essential part of the process of cure lay in the overcoming of these resistances and that unless this was achieved no permanent mental change could be brought about in the patient" (6). He maintained this position to the end of his life stating, for example, in 1937: "The therapeutic effect of analysis depends on making conscious what is, in the widest sense, repressed within the id" (6).

These statements of the essential tasks of analytic therapy are a direct and obvious corollary of Freud's theory of neurosis; and go hand in hand with the proposition that lasting recovery from neurotic disorders is not to be expected without the work of analysis having been effected. Now, it has turned out to the contrary, that remission of neurotic symptoms obtained without the use of analytic procedures is almost always lasting. In other words, what psychoanalytic theory holds to be necessary for enduring recovery is in fact not necessary. Does this imply that what the theory proposes as the basis of neurosis is in fact not the basis?

This conclusion would seem an exceedingly likely one in any instance in which the requirements for cure are dictated by a causal hypothesis. To take a case analogous to that at issue: suppose that many years ago, before the etiology of malaria was established, the hypothesis had been put forward that plasmodia play a necessary part in the cause and maintenance of the disease. It would have seemed to speak strongly against this hypothesis if (in contrast to what was actually found) it had turned out that patients regularly became permanently free from symptoms while the live parasites continued to populate their blood cells. Nevertheless, the causal role of the parasites could not have been absolutely excluded on this finding alone. It might have been suggested that they were encapsulated, for example.

In the field of neurosis theory, Freudians aware of the fact that symptoms may disappear without analysis have proposed that this may be the result of increasing or deepening repression. But it is consistent with their theory that they do not regard such disappearance as likely to endure. Fenichel (5) states that when therapy has produced re-

pression of symptoms, "the pressure of the repressed will necessarily be increased and sooner or later new symptoms will be formed." Since permanent repression is not seriously entertained by the theorists, insofar as our evidence demonstrates failure of new symptoms "sooner or later" to appear, it seems to render abandonment of the repression theory almost inescapable. If the alleged unresolved repressed permanently fails to produce symptoms, then either it has no real existence or it is irrelevant to symptoms.³

There are factual as well as theoretical considerations that discourage the invocation of permanent "repression" as a way out of the Freudian dilemma. The theory expects some disadvantage for the patient with intensified repression in comparison with patients in whom analysis has brought about a "real undoing of the pathogenic defenses" (5). However, studies that have broadly compared the results of psychoanalysis with those of other methods have not indicated any superiority in the *quality* of cures obtained by psychoanalysis (12, 19). Two recent reports of the therapeutic experiences of individual psychoanalysts tend to confirm this finding. Stevenson (17) noted that a group of his patients who were treated by direct instigation of changes in behavior did not seem in any respect worse off than others whom he treated by psychoanalysis. Ellis (3) presents data showing that his results improved increasingly the further he deviated from psychoanalytic methods.

(b) *Do variants of Freudian theory offer a way out?* Modern deviations from Freudian theory (e.g., Horney (11) Fromm (7), and Alexander (1)) are mainly in the direction of giving greater importance to unconscious conflicts related to the immediate situation of the patient. Horney (11) denies that there is an actual persistence of

³ The whole of the foregoing discussion may make it appear that I accept the regular occurrence of repression in neurosis but doubt its causal role in producing symptoms. The truth is that I believe that something resembling repression occurs only rarely. The general tenor of my argument is: even if we assume that repression is a universal concomitant of neurosis, it fails to account for the facts concerning recovery from neurotic symptoms.

repressed infantile wishes and fears, and holds that what is preserved is a character trend based on the early experiences. She believes *current* conflicts are repressed to defend the patient from pain. But the basis of neurosis is still repression, and procedures that deal with "defenses" remain the essence of therapy for her. While Fromm(7) emphasizes the influence of socio-economic factors on personality, his dynamics of individual neurosis remain basically Freudian. Alexander(1) gives importance to insights or semi-conscious consolidations of insight that follow on the interpretations made during therapeutic sessions.

These examples reflect deviations in matters of detail, not principle. The road to recovery is always by way of dealing with the defenses that keep the repressed unconscious. Ruth Munroe(15) states the following to be common to the therapeutic approaches of Adler, Horney, Fromm and Sullivan :

The crux of the therapeutic process for these schools as well as for the "Freudians," may be stated as the development of *insight*. This does not mean, of course, mere *intellectual* appreciation of the complex of conscious and unconscious patterns operating on one's personality ; it means the actual *experiencing* of aspects of one's personality which have been made *defensively* unconscious.

These modifications of Freudian theory thus do not render it any less vulnerable to our observations than the original theory. It seems just to say that if freedom from symptoms is almost invariably lasting when procured without the use of analytic methods, *painful unconscious conflicts are almost certainly not the fountainhead of neurotic symptoms*. This is no startling conclusion when the weaknesses of psychoanalytic theory construction are realized(22).

(c) *Implications for a theory of neurosis as a phenomenon of learning*. In recent years, a theory has been proposed according to which neuroses are persistent unadaptive learned (conditioned) reactions acquired in anxiety-generating situations(4, 20, 21). Experimental neuroses corresponding to this definition have been produced in animals by subjecting them, while in confined space either to ambivalent stimulus situa-

tions (e.g., Pavlov, 16) or to noxious stimulation(14, 21). Enduring habits of disturbed reaction to definable stimulus situations are produced. These habits can be systematically eliminated if conditions are so arranged that the neurotic response can be inhibited on repeated occasions by the simultaneous elicitation of an incompatible response that is "stronger" than the neurotic response.

The regularity with which the neurotic responses can be eliminated in this way led to the formulation of the general hypothesis that *if a response inhibitory to anxiety can be made to occur in the presence of anxiety-evoking stimuli so that it is accompanied by a complete or partial suppression of the anxiety response, the anxiety response habit will be weakened*. This hypothesis has been tested in relation to human neurotic habits of response, counterposing to anxiety in suitable contexts a variety of responses (e.g., deep muscle relaxation), that are physiologically antagonistic to anxiety. It has been found that, as in the animal experiments, progressive decrements occur in the strength of anxiety responses to relevant stimuli. In terms of outcome, in 3 successive series of neurotic patients, comprising a total of 210, the percentage either apparently cured or much improved has consistently been about 90(21).

These therapeutic observations support the view that neurotic behavior is a particular case of learned emotional behavior with special features(20, 21) and removable by unlearning. Such unlearning occurs whenever neurotic responses are inhibited by incompatible responses ; and this may happen whether by design or not in *any kind* of therapeutic interview situation and *also* in the life situation. It is apparently because interviews of all kinds generate emotional responses inhibiting anxiety evoked by verbal stimuli that similar percentages of favorable results are obtained by a large variety of therapies other than therapy based on principles of conditioning (21).

Our theory postulates, in accordance with experimentally established knowledge about learning, that once a neurotic habit of response to specified stimulus conditions has been eliminated, such elimination is perma-

nent unless the habit is reinstated by specific new conditioning (learning). The facts revealed in the follow-up studies reviewed in this paper favor this postulate.

SUMMARY

A survey of follow-up studies comprising 249 patients whose neurotic symptoms have either ceased or improved markedly after psychotherapy of various kinds other than psychoanalysis shows only 4 relapses (1.6%). This evidence contradicts the psychoanalytic expectation of inferior durability of recoveries obtained without psychoanalysis and does away with the chief reason for regarding analysis as the treatment of choice for neurotic suffering. The facts presented have gravely damaging implications for the whole psychoanalytic theory of neurosis, but accord with a theory based on principles of learning.

DIFFERENTIAL ASSESSMENT OF POSTHOSPITAL PSYCHOLOGICAL FUNCTIONING : EVALUATIONS BY PSYCHIATRISTS AND RELATIVES ¹

BENJAMIN PASAMANICK, M.D., AND LEONARD RISTINE, M.D.²

A previous paper dealing with psychiatric orientation and its relation to diagnosis and treatment in a mental hospital indicated that (a) great inter-ward variability existed in the diagnoses made of patients even though patients were assigned to the different wards almost solely on the basis of available bed space, (b) diagnoses of patients on the same ward varied considerably with changes in administrators on the ward, (c) psychiatric orientation rather than patient behavior accounted for much of the variability in diagnoses, and (d) the differences in diagnosis were reflected in the care and treatment provided patients(1).

This paper is concerned with the same problem of variability of diagnosis and its significance but from another point of view, and in circumstances in which psychiatric orientations are similar or minimally divergent.

In this study 287 female patients consecutively released from a mental hospital have been studied 6 months after hospital discharge. Patients and their significant others were interviewed in an attempt to determine factors associated with success or failure in outcome and with the level and adequacy of patient performance. Apart from rehospitalization, the 3 principal measures of case outcome have been psychological functioning, domestic role performance and the extent and types of social participation of former patients. Social factors thought to be importantly related to case outcome and deserving of empirical testing have been such variables as the family situation of the former patient, living arrangements, social class, degree of deviant behavior by significant others, the expectations of significant others and the like(2).

In order to have an evaluation of the level or adequacy of posthospital patient functioning, independent of that derived from the significant other, a random sample of former patients was asked to cooperate by presenting themselves for a psychiatric interview. Two hospital psychiatrists were involved in these evaluations, and former patients were assigned to one or the other purely by chance. Neither psychiatrist was aware of the patient's previous history except as he may have deemed it advisable to ascertain this during the course of the interview.

The results of these evaluations will be presented in this paper. First, the 2 psychiatrists will be compared with each other in terms of (a) their Lorr Psychiatric Scale ratings for the patients they interviewed, (b) their specifications of the degree of impairment of the patients they saw, and (c) their diagnoses of these patients. The latter will be compared with the diagnoses given the patients at discharge. Second, the ratings and evaluations regarding the adequacy of functioning of each patient given by each of the psychiatrists will be compared with similar ratings given the patient by her significant other. In other words, the perceptions and insights of the psychiatrists will be contrasted with those provided by husbands or other significant others. This will also serve to retest our previous finding that the psychiatrist generally specifies a greater degree of impairment for the patient than does her significant other(3).

METHOD

In an 8-month period, December, 1958, through July, 1959, the Columbus Psychiatric Institute and Hospital, a short-term, intensive therapy institution, discharged 376 female patients. Of these, 89 were either returned to communities outside the 13 county areas served by the hospital or were reinstitutionalized within 15 days after dis-

¹ This study was supported in part by Grant M-2953 from the National Institute of Mental Health, United States Public Health Service.

² Respectively, Prof. of Psychiatry and Director of Research, and Associate Professor of Psychiatry, Columbus Psych. Inst. and Hosp., Col. of Med., Ohio State University.

charge. This left 287 cases who were followed in the community. Of the 287 former patients, 41 or 14% were reinstitutionalized within 6 months after hospital release. The remaining 246 cases represent the pool from which 119 were requested, on a random basis, to return for a psychiatric assessment. Despite a great deal of encouragement, only 65 of the 119 or 54.6%, cooperated in the psychiatric re-evaluation program.

The 65 re-evaluation patients were found to be similar to the 54 refusal cases in almost every respect in which available data permitted comparison. These included 16 hospital variables, *e.g.*, diagnosis, previous admissions, an impairment rating at admission and one at discharge, hospital treatment and outpatient treatment. The 2 groups were also similar in their social background characteristics including age, social class standing, education, religion and size of community in which they resided. They differed only in their marital status. The re-evaluation cases included a significantly greater percentage of married women (70%) than did the refusal cases (41%). In addition, on none of the variables—pre- and post-hospital and social background—did the re-evaluation subjects differ from the 127 cases who were not selected to participate in the psychiatric assessments. This would lead to the conclusion that no appreciable selectivity characterized the psychiatric assessment cases or differentiated them from the refusals or those not involved in this aspect of the outcome study.

Minimal differences existed in the orientations towards diagnosis and treatment of mental patients and towards the etiology of mental disorders in the 2 hospital psychiatrists who participated in the psychiatric assessments. One of the psychiatrists saw 39 former patients, the other 25 former patients. This difference was due wholly to scheduling and time factors since patients were assigned randomly to them.

Each of the physicians interviewed the patients without prior access to case materials. At the conclusion of the interview, which usually exceeded 1 hour in duration, a Lorr Psychiatric Rating Scale form, Part I, was filled out by the examining physician. In addition, the psychiatrist also rated the degree of psychiatric impairment character-

izing the patient as he perceived it at the time. The degree of impairment ranged from 0-100. Finally, the physician specified the diagnosis to be given the patient. Diagnoses ranged from no mental illness present through the usual psychiatric categories.

The major instrument, the Lorr Psychiatric Rating Scale, Part I, contains 42 items pertaining to behavioral and psychological functioning. Each item presents the possibility of rating the degree of variation from a "norm" population. The total norm score is 48.5.

We departed very slightly from the procedure specified in the manual of instructions. Two items, 14 and 26, which deal with physical disability were excluded. Our total score, based on discrepancies from the item norms, became 40 for no visible impairment to 151 for complete and total disability. Also omitted from analysis were the factor scores since these served no useful purpose in this particular study.

In addition to the ratings derived from the psychiatric interviews, relatives (usually husbands) had previously evaluated the psychological functioning of the patients. Each significant other had rated the patient on 32 items of psychological functioning, of which 17 paralleled those in the Lorr Scale. Hence, it is possible to relate skilled psychiatric judgments on these items to those of the less skilled but more familiar ones of the significant others.

FINDINGS

Inter-Psychiatrist Ratings: Although the patients seen by the 2 psychiatrists did not appear to differ from each other either in terms of objective criteria or in the perceptions of their significant others, they were evaluated differently by these psychiatrists. One (A) rated his 25 patients as being more ill than did the other (B) who evaluated 39 patients. The patients of the former received an average Lorr Scale score of 57.1 while the latter averaged 49.1, a difference which is statistically significant. Of the 40 individual items, psychiatrist A indicated that his patients departed more from the norm on 26 items, less on only 12 items and not at all on 2 items, compared with the patients of the other psychiatrist. On 12 of the 40 symptom items, the patients of

				Perplexed by problems	36	23	—
				Fear of future	76	23	.01

psychiatrist A were rated significantly more deviant than those of the other psychiatrist. As indicated in Table 1, twice as many of the patients rated by physician A were tense and nervous, deviated from the norm on hostility, showed pronounced mood swings, and indicated an unrealistic self estimation. Compared with B, psychiatrist A found 3 times as many of his patients made use of somatic complaints to get attention or control others, were preoccupied with their health, were too loud or inaudible in their speech, and feared the future. Other symptom differences were of the same or greater magnitude.

This analysis would seem to indicate that the 2 raters were emphasizing different aspects of behavior or symptoms and that one was systematically specifying greater impairment than the other and perhaps a less

optimistic prognosis. Such, however, was not the case. When asked to rate the psychiatric disability of their patients on a scale ranging from 0-100, it was psychiatrist B, and not A, who specified the greater impairment. Thus, physician A indicated an average disability rating of 25% while the average impairment rating given the patients by physician B was 29%. This reversal, though not statistically significant, would indicate that clinical judgment involves more than simply rating symptoms. It involves a weighting and an order which is superimposed on what is actually seen. Consequently the difficulty is obtaining reliability among qualified raters.

During the course of their hospital stay, 64% of the 25 patients of psychiatrist A and 54% of the patients of psychiatrist B had been diagnosed as psychotic. Schizophrenics

accounted for 28 and 33% of their respective patients. Six months after discharge, physician A found no visible signs of mental illness present in 20% of the cases and physician B in 18% of his patients. The percentage of psychotics in the 2 populations were 44 and 43% respectively and 16 and 23% of the 2 populations were classified as schizophrenics. No pronounced shifts occurred in the diagnoses given the patients 6 months later except for the nearly one-fifth in each group now designated as not being mentally ill. Further, there is nothing in this area of diagnosis sufficient to account for the discrepancies of the two physicians on the Lorr Scale ratings of the patients. If anything, the patients of psychiatrist B should have been somewhat higher in disability score since the percentage of schizophrenics among his patients was slightly greater.

Psychiatrist-Significant Other Ratings: Prior to their psychiatric re-evaluations, each of the patients had been rated by their significant other (usually the husband) on a 32 item scale of psychological functioning. Most of these 32 symptoms or behavior items were derived from the Lorr Scale, Parts I and II, although their wording was changed so as to be more comprehensible to laymen without specialized knowledge. Seventeen of these symptom items are directly comparable in the ratings of significant others and of the 2 psychiatrists.

The findings indicate (a) that the significant others of the patients later evaluated by either psychiatrists A or B, did not differ in their appraisals of these patients, (b) that when they differed significantly from the significant others, psychiatrist A tended to rate his patients as more deviant from the norm than did their relatives, and (c) that in the case of psychiatrist B, the opposite prevailed. The relatives of his patients specified more frequent impairment on the symptom items on which they differed greatly.

A. Significant Other Comparison: Table 2 indicates that the significant others of the patients of psychiatrist A perceived their relatives as functioning at about the same level of impairment as did the significant others of the patients of psychiatrist B. According to their relatives, more of the patients of psychiatrist A were malfunctioning, on 9 items, fewer on 7 items, and no dif-

ference could be found on 2 items. The pattern of impairment seemed wholly comparable for the 2 groups.

B. Psychiatrist A and Significant Others: Since the 2 psychiatrists were found to differ in their evaluations of patient functioning, it was necessary to compare each individually with the significant others of the patients he interviewed.

Table 3 presents a comparison on the same 17 symptom items for psychiatrist A

TABLE 3

A Comparison of the Percentage of 26 Patients Seen by Psychiatrist A and Rated by Significant Other as Exhibiting Each Symptom

	SIGNIFICANT A	PSYCHIATRIST OTHER	P
Non-relevant responses	36	20	—

People talk about her	36	24	—
Fears future	76	28	.01
Worries about bodily organs	76	24	.01

and the significant others of his patients. There are only 4 symptom areas in which disagreement occurs which could not be attributed to chance. In each instance the qualified rater specifies the greater disability. Three of the items deal with the patients' somatic complaints and the fourth with apprehension about the future. It can only be surmised in interpreting these ratings, that the psychiatrist was greatly concerned with the somatic condition of the patient in relation to other facets of post-hospital functioning. It may also be that significant others do not consider somatic ailments to be important in mental illness. On the major symptoms associated with mental illness, only minor and random discrepancies existed between psychiatrist and significant other. Finally, the correlation between psychiatrist A and significant others, using the entire 40 item Lorr Scale score and

the 32 item psychological functioning index was $+ .71$ —a very high and significant correlation which, as already indicated, would have been even higher except for differences in the somatic conditions section of the indices.

C. Psychiatrist B and Significant Others: While one pattern of differences emerged in the ratings of psychiatrist A as opposed to the significant others of his patients, another type of pattern was found to characterize the ratings of psychiatrist B and patients' significant others. First, psychiatrist B tended to perceive less malfunctioning in these symptom areas than did the significant others. This finding is presented in Table 4.

TABLE 4

A Comparison of the Percentage of 39 Patients Seen by Psychiatrist B and Rated by the Significant Other as Exhibiting Each Symptom

	PSYCHIATRIST B	SIGNIFICANT OTHER	P
Non-relevant responses	21	15	—

Suicidal thoughts	21	5	.05
People talk about her	8	26	.05
Fears future	23	36	—
Worries about bodily organs	23	23	—

Second; when significant differences in the 2 sets of ratings were found, the psychiatrist with one exception stipulated less impairment than the significant others. The one exception occurred with regard to self-des-

tructive impulses on the part of the patients. Third, no single area of behavior or symptoms served as the focus of differences between skilled observer and significant others as did somatic complaints in the case of psychiatrist A. Fourth, the correlation between the ratings of psychiatrist B and the significant others was lower, $+ .50$, than the correlation for the other rater and his significant other comparisons. This lower correlation again attests to the greater randomness of differences throughout the ratings. In sum, then, psychiatrist A over-rated impairment in one area and psychiatrist B under-rated it in most areas when the significant others are used as the reference group.

DISCUSSION

In interpreting these results two general conclusions seem important. The first concerns the importance of relatives of patients as raters of the illness and functioning of their significant others. The second reveals that when psychiatric orientation differences between qualified and experienced psychiatrists are minimized, they tend to agree on the general level of disability of their cases and on the diagnoses which they make. Differences, however, continue to occur on the specifics of functioning and the importance and weight of these for the clinical picture of the patient. It is unlikely, as a consequence, that any instrument which attempts to reduce clinical judgment to a series of symptoms or behaviors will be very reliable unless practitioners are first schooled in its usage. Under such conditions variable biases will be replaced by systematic bias leaving us still very short of the desired goal of valid judgments and measures of psychiatric impairment and illness.

Three points should be stressed in interpreting the ratings made of patients by their relatives. 1. Significant other judgments seem to be most reliable when they concern the actual day-to-day functioning of the patients. Relatives seem competent to judge overt and meaningful deviations in functioning. Continuing contact with the patient gives the relative some perspective over time as well. However, relatives and for that matter trained and experienced practitioners

tend to run into difficulty and confusion in rating or judging such subjective, ill-defined and abstract concepts as hostility, guilt, insecurity and the like. The dilemma then involves either eliminating such difficult to qualify but important concepts from rating scales, or retaining them and introducing inevitable perceptual and conceptual biases.

2. Elsewhere we have shown that relatives of former mental hospital patients, and relatives of never hospitalized women who served as controls for the patients clearly were able to distinguish the functioning of the 2 groups. On 20 of 32 symptoms, the controls were rated by their relatives as superior functioners. Thus, using overt behavior or symptoms it is possible to validate the ratings of relatives. This surely has important implications for epidemiologic studies of mental disorder in the general population or in various sub-cultural groups.

3. In the division of labor in the mental health area, it is frequently the lot of the social worker to obtain case histories from relatives. The physician or therapist is often, therefore, denied the salutary effort of tempering or modifying or affirming his own judgments by getting these materials either already interpreted for him or possibly not getting them at all except for some social background data. If, as we have tried to indicate, the relatives and significant others are capable of making critical judgments of patient functioning, then these ought to become available, undiluted and uninterpreted by others, to the clinician. These observations seem to point up the necessity for thorough training of psychiatric residents in the securing of reliable anamneses from the relatives by patients. This appears to be badly neglected in present day psychiatric training.

As suggested elsewhere, the two psychiatrists in this study were selected because they were only minimally discrepant in their orientation. Despite this, differences in their evaluations did occur. Neither their differences in age nor experience, both of which were substantial, could account for the fact that one tended to see greater symptom impairment in his patients while the other tended systematically to underrate such disabilities. Perhaps the difference can be

accounted for by the general pessimism of the more experienced clinician as to case outcome and the apparent optimism of the younger clinician in this respect. Whatever the explanation, it remains a fact that the perceptions of relatives coincided to a greater extent than the evaluations of our skilled practitioners. Finally, the extent to which differences between psychiatrists A and B could have been removed had they interviewed relatives as well as patients is a moot point which remains to be tested empirically.

RELAXANT ANAESTHESIA FOR ELECTROPLEXY¹

S. V. MARSHALL, M.B., CH.M.²

Modified electroplexy was used for the first time in Australia on December 1, 1945 (27). Since then relaxant anaesthetics have been used in this series for 16,275 treatments in 2,100 cases. All these anaesthetics were given by trained anaesthetists, 13,961 by myself and 2,314 by associates.³ The series comprised 639 males and 1,461 females; age-range 13 to 89, average 50 years. Practically all these patients were of private or intermediate status.

DEVELOPMENT

Case 1.—Stout female, 56; involuntional melancholia for 18 months. Early in illness fractured neck of L. femur; pin-fixation performed. Hence electro-convulsive therapy withheld, but finally decision made to try it with curare (7, 8).

In 5 weeks 11 treatments given; no aggravation of injury. Each fit well modified by Intocostrin equivalent to 20-25 mgm. of d-tubocurarine. No preliminary anaesthetic used, and despite pause of 3-5 minutes between injection and stimulus, little anxiety seen until the last few treatments. Excellent mental recovery ensued.

At this time curare, although available in purified form (Intocostrin), was still regarded with suspicion, and had been employed by us in surgery for only a few months (9). Nevertheless, it was felt that in the new application efficient pulmonary ventilation with oxygen would provide the essential safeguard. This view has been amply confirmed by subsequent experience.

Unexpectedly, in this case and several others given Tubarine, the recovery of breathing was little delayed, perhaps because of excess acetylcholine produced at

the neuro-muscular junctions by the intense motor discharge. This was fortunate because the value of neostigmine was then not sufficiently appreciated by us.

Decamethonium (Eulissin; Syncurine) and gallamine (Flaxedil) were next given a trial. Full dosages, 5 and 80 mgm. respectively, were found necessary, and the persistence of apnoea for anything up to 10 minutes or more afterwards not only demanded efficient and sustained artificial respiration but also made the procedures unduly time-consuming. However, psychiatric misgivings about the safety of these methods so restricted their use that in 6½ years only 11 cases (65 treatments) had been dealt with.

The introduction of succinylcholine (suxamethonium) chloride (Scoline, Anectine) now revolutionized the situation. Following the first British report (31) it soon came to Australia (1) and its value in ECT was rapidly confirmed there (29, 32). My own recourse to the new drug so increased that, during the years 1957 and 1958, 816 cases (6,184 treatments) were handled. Numbers have declined somewhat since then, probably because of improved tranquillising or anti-depressive drugs.

Periodically suxethonium bromide (Brevetil E) was tried in this series (35 cases), but its one advantage of slightly briefer action was offset in terms of cost, convenience, constancy, relative potency and stability in solution. Far more than with suxamethonium chloride its solutions require cold storage to preserve their potency, which otherwise deteriorates rapidly. Thus increased volumetric dosages will more frequently become necessary with suxethonium solutions that are kept for even short periods, while consequent variations in residual potency create doubts about the likely response, which might be unexpectedly violent.

Suxamethonium bromide (Brevetil M) was also found to have similar disadvantages. As with suxethonium its relatively low content (64%) of active cation compares

¹ Read at the 2nd World Congress of Anaesthesiologists, Sept. 8, 1960, Toronto, Canada.

² Harley, 143 Macquarie St., Sydney, N.S.W., Australia.

³ It is desired to thank Dr. Cedric Swanton, Dr. Stephen Benedek, Dr. Roger Kiely, and Professor W. S. Dawson for giving me access to most of the patients dealt with in this paper. The invaluable help of the nursing staffs of the hospitals concerned is also acknowledged, as is that of my stenographer, Mrs. M. Mitchell.

unfavorably with that of 80% for the chloride(11). This latter figure facilitates the calculation of accurate dosages when necessary. Hence in this series the preference for suxamethonium chloride has been maintained.

SCOPE

Increasing familiarity showed that, in competent hands, modified electroplexy could be made safe for virtually all patients needing it. Training and experience in modern anaesthetic technique was an invaluable aid in this regard. The essential requisite for safety was skilful and efficient pulmonary ventilation with oxygen during every treatment.

The following brief reports are illuminating :

Case 20.—Emaciated female, 50 ; severe melancholia. Extreme osteoporosis absolutely precluded unmodified ECT. Recovery after 12 treatments modified variously with Brevedil M, Scoline, and Brevedil E.

Case 219.—Big-framed florid woman, 65 ; post-reserpine depression. Gross hypertension, 300/200. Retinal changes present. Good result from 10 treatments, oxygen inflation with each. Further treatments 8 months later with good effect.

Case 1133.—Frail old woman, 70 ; senile depression. Coronary sclerosis, hypertension and congestive cardiac failure ; on digitalis and Diamox. Mental improvement with 17 treatments, modified with Scoline, over 5 months. Alarming bradycardia, extrasystoles and hypotension at first treatment, corrected by O_2 inflation and IV atropine. Similarly protected in subsequent treatments, plus dilution and slow injection of all solutions.

Case 1321.—Cyanotic female, 60 ; gross hysterical "asthma," 3 years. On enormous doses of adrenaline. In hospital 12 times with "status asthmaticus." Appearance really shocking. Recovery after 7 treatments modified with Scoline. Relapse 4 months later, 7 further modified treatments only temporarily effective. Now in "institution ; probably denied further treatment because of terrifying "symptoms."

Case 1357.—Debilitated male, 68 ; involutional melancholia ; myocardial degeneration, with 2:1 heart-block ; cardiac failure imminent ; on digitalis. Excellent mental recovery after 11 treatments modified with Scoline ; improvement maintained.

Without prompt and sustained IPPR⁴ with oxygen in these patients, their prospects of survival would have been very uncertain. A similar consideration applies to several cases of prolonged apnoea, quoted later. Treatment was denied in only two cases, one of advanced congestive cardiac failure, and another, restored with oxygen and saline venoclysis from collapse following thiopentone, found to have a perforated duodenal ulcer.

TECHNIQUE

From an early stage in this series a "sleep-dose" of thiopentone has been given to all patients treated. The 2% solution was always used, especially to minimize irritation from wrong placement (perivenous or intra-arterial injection). A good sign of correct location is that the patient becomes aware of a sulphurous smell or taste within 3 or 4 seconds of starting the injection, perhaps because of some breakdown of the barbiturate in the lungs. Salivary excretion could not occur in this short time.⁵

A pause of about 5 seconds was then observed before giving the relaxant, so that painful muscular twitchings and feelings of suffocation would not be appreciated by the patient. All relaxant solutions, too, were well diluted with sterile water for the following reasons :

a. Any minor leakage or loss of a concentrated solution will reduce significantly the quantity of active substance given, whereas with free dilution small losses become immaterial.

b. Increasing the volume of the injection will lessen the possibility of its sequestration in dilated or obstructed veins.

c. The larger volume necessitates a slower rate of injection, thus ensuring better dilution in the blood-stream and reducing the possibility of muscarinic (vagal) effects on the heart(23).

On completing the injections, rhythmic inflation of the lungs with oxygen was practised, to prevent hypoxia during the 50-70 seconds required for maximal effectiveness of the relaxant. Few reports have stressed the importance of this pause, which influ-

⁴ Intermittent positive pressure respiration.

⁵ "I feel it in my throat." "It's going up through my nose." "What a horrible taste." "It stinks."

ences dosage significantly (*vide infra*). The stimulus was then applied, and when muscular spasms had ceased oxygen-inflation was resumed and continued until spontaneous breathing recommenced.

Throughout the whole procedure firm chin-support was consistently applied, not only to ensure a clear airway and to safeguard the tongue, lips, and teeth, but also to keep the epiglottis away from the posterior pharyngeal wall and so to prevent reflex spasm or vomiting. This is most important, in case food or drink has been surreptitiously taken—indeed, it is a useful safeguard when the stomach is known to contain food. For similar reasons artificial airways and mouth-gags were generally avoided, and sound (acrylic) artificial dentures left *in situ*. When breathing resumed, all patients were placed in a true lateral position, so that a clear airway and the escape of secretions would be ensured during recovery. To leave patients lying supine at this stage, partly obstructed and gargling their secretions, is bad practice.

DOSAGES

Preliminary atropine was usually omitted, so as to minimize discomfort. When, however, hypersecretion or marked bradycardia had been found to occur, 0.65 mgm. (gr. 1/100) would be given hypodermically about one hour beforehand. If time were short, or in emergency, atropine was given intravenously—a rare necessity.

The usual dose of thiopentone varied between 150 and 250 mgm., depending on the physical and mental condition of the patients. Occasionally more would be used. Obviously, heavy medication beforehand (barbiturates; chlorpromazine, *etc.*) would suggest reduced dosages.

Similarly, no minute calculation of dosage was necessary as regards the relaxants. Experience showed that, with succinylcholine chloride, the range was from 15 to 50 mgm., also depending on the nutrition and physique of the patients. Usually, the first treatment represented the trial of a roughly estimated dose, subsequent requirements being regulated according to the response then obtained. Formerly larger dosages (50-100 mgm.) were considered necessary, not only from anxiety to procure adequate

relaxation but also because insufficient time (20-30 sec.) was being allowed between the injection and stimulus. Later it was realized that by giving the relaxant enough time to act, its dosage could be very substantially reduced without loss of efficiency. A more speedy recovery of breathing also resulted.

RESPONSE

In this series the object has been to obtain good modification of the convulsion, especially of the initial tonic spasm, without suppressing the indications of a major fit. Profound modification was sought only when serious traumatic or other disabilities already existed, but it sometimes occurred when not really desired, usually at initial treatments. The reverse situation of unexpectedly strong convulsions usually meant deterioration or wrong placement of the relaxant solutions, or use of the wrong drug. This occurred twice, with nikethamide (Coramine) and methyl-amphetamine (Methedrine) respectively in Cases 95 and 181, without ill effects.

There are various useful but not consistent signs that a major fit is taking place. Following the brief stimulus the tonic phase is sustained, with spastic dorsi- or plantar-flexion, and often internal rotation of the feet. The great toes are either flexed or extended, sometimes with reversal of this movement when the clonic phase begins. Similarly, acute flexion of the wrists and fingers often occurs, but with the thumbs adducted and the index finger pointing ("J'accuse"). The lips are also strongly pursed ("duck-face") and the brow creased in bewildered perplexity. Occasionally the pupils are dilated or the eyes widely opened. Clonic spasms or tremors now follow, and are confirmatory of a major seizure, even if slight and confined to the eyelids and face. Undue delay between injection and stimulus (over 90 seconds) will result in a prolonged clonic phase, because the effect of the relaxant is now rapidly waning. If, however, no sign whatever appears, the stimulus may be repeated when breathing (and hence neuro-muscular transmission) returns, and a good response obtained. Meanwhile, of course, rhythmic inflation with oxygen is continued.

COMPLICATIONS

There was no death immediately related to the therapy in this series, but 2 patients died during the course of their treatments. One had a cerebral haemorrhage about 12 hours after her 4th treatment, while the other died of a coronary occlusion 4 days after her 5th treatment. Both of these events were thought to be purely coincidental. Otherwise, the only significant complication was prolonged apnoea, which developed in 9 cases. Although more likely in the malnourished and debilitated, it nevertheless occurred in some apparently healthy subjects. Whatever the cause, whether deficiency of pseudo-cholinesterase in the blood-serum (16) or of potassium ions at the neuromuscular junctions (13, 24), the essential treatment is to maintain efficient pulmonary ventilation with oxygen for as long as necessary. In addition, if apnoea persists for more than a few minutes, carbon-dioxide absorption must be practised as well, to prevent the toxic effects of hypercapnia. These are far more dangerous, especially to the heart (22, 18) than any prolongation of the apnoea by hyperventilation which indeed, by inducing alkalosis, would favour elimination of the relaxant (17).

This observance of anaesthetic principles forbade the use of stimulants and analeptics, that are so often given priority by various writers, especially psychiatrists. There is no need to abandon modified therapy because of such apnoeic incidents; in subsequent treatments the dosages of the relaxant can be drastically reduced, as little as 5 mgm. of suxamethonium often being adequate.

A variety of minor complications also occurred in this series. Thiopentone was given intra-arterially in two cases, but being well diluted (2%) produced no ill effect. Venous thrombosis was similarly limited, an important consideration when scanty veins must be conserved for multiple injections. Post-anaesthetic restlessness was rare, because of the use of oxygen. Undue bradycardia, salivation and laryngospasm occurred in a few cases; in these atropine was useful. A dusky colour in two cases, unrelieved by oxygen, was due to sulphaemoglobinaemia from excessive use of phenacetin compounds. Another case with deficient response to, oxygen, required

bronchoscopic evacuation of massive pus accumulations from the lungs. The hazard of bronchial inundation with pus should always be anticipated in patients with bronchiectasis or chronic sinus infections, and suitable preliminary therapy—postural drainage and bronchoscopy—effected. Temporary signs of a partial brachial plexus lesion were seen in one case, probably due to cervical spondylosis. Finally, vulcanite dentures were broken in two cases; artificial teeth of this material are now removed. Complaints of after-pains were rare, since 4 hours bed-rest was ensured after all treatments.

COMMENT

The relevant literature exhibits much diversity of opinion regarding the proper conduct of modified electroplexy (2). Much false emphasis is also evident. For example, haemorrhagic lesions found at autopsy have been attributed rather to the therapy than to the most likely cause, anoxia (25). Deaths occurring after giving the relaxants but before the stimulus was applied have been attributed to the former, and not to the ineptitude of the users (20). Some writers consider that restriction of both thiopentone and relaxant to barely effective dosage will increase the safety margin (21, 28). This idea has been extended to justify the entire omission of thiopentone (15), a "sub-shock" being used instead to produce unconsciousness (19, 10). Criticism of this most unpleasant treatment has been made (26), for in competent hands there is no need to restrict either the anaesthetic or the relaxant components of the procedure.

The ill-effects of oxygen deficiency are not sufficiently emphasized in articles on this subject. It is often mentioned only vaguely or as a secondary consideration. Some reports do not refer to it at all, but instead exhibit a pathetic reliance on such drugs as lobeline, nikethamide, aminophyllin, potassium chloride, nor-adrenaline and even cortisone in emergency situations. Even anaesthetists have been guilty of stating that oxygen is "not often required" or "given only when necessary." It is always necessary, for serious impairment or suppression of the vital function of breathing invariably accompanies modified electroplexy. To

be effective oxygen must reach the pulmonary alveoli, and this can be ensured only by inflation of the lungs from a Waters' "bag-and-mask" or similar outfit. Failing this, expired-air inflation (mouth-to-mouth, etc.) is far superior to manual compression of the thorax. The futility of even massive insufflation of oxygen into the nose or pharynx of a paralysed subject should be obvious to everyone.

Further examples of false emphasis are readily found. In an otherwise excellent article(3) a death is ascribed to "severe functional disturbance of delicately balanced physiological mechanisms"—in short, asphyxia. Again, in a fine study of prolonged apnoea after the use of Brevedil E(4) it is stated that this drug can produce "not only apnoea but a profound degree of collapse"—hyperbole indeed. Further, the use of an oxygen and 5% carbon-dioxide mixture is then recommended. This advice, of course, ignores the fact that central stimulation cannot improve breathing while neuro-muscular transmission is interrupted. The fallacy of using this mixture to prevent hypocapnia from over-vigorous lung-inflation(30, 12, 15) also should be obvious.

Hypoxia during surgical anaesthesia is known to cause mental deterioration, especially in elderly subjects(5, 6). It is probable that repeated hypoxic episodes during serial electro-convulsive treatments could be similarly deleterious, so reducing the prospects of good mental recovery. Hence efficient ventilation of the lungs with oxygen should invariably accompany modified electroplexy. Knowledge and skill in this regard are largely the prerogatives of trained anaesthetists. Others wishing to utilize effectively this vital remedy should either know something of its proper application or else call in expert help.

SUMMARY

1. A report covering 16,275 modified electro-convulsive treatments on 2,100 patients is submitted.

2. The scope and development of the procedure in the course of nearly 15 years is indicated.

3. The technique and dosages employed with the preferred drugs, thiopentone and suxamethonium chloride, are outlined.

4. There was no death immediately related to the therapy, but 2 patients died coincidentally during the course of their treatments.

5. Prolonged but non-fatal apnoea occurred in 9 cases, being readily controlled by proper oxygen therapy. Other complications were rare and of minor character.

6. The imperative need for such oxygen therapy in all patients subjected to modified electroplexy is emphasized.

7. Comment is made on various examples of false emphasis, especially regarding emergency developments, that occur in the relevant literature.

8. The possibility that repeated hypoxic episodes in elderly or debilitated patients might impair mental recovery is stressed.

MONISM AND DUALISM IN THE STUDY OF BEHAVIOR : IS THERE A CONFLICT BETWEEN THE PSYCHODYNAMIC AND THE ORGANIC POINTS OF VIEW ?

MAX LEVIN, M.D.¹

Bailey(1), who has devoted much time and thought to the mind-brain problem, begins his recent penetrating analysis of the subject by defining the sharp contrast, as he sees it, between the biological and psychodynamic points of view. He says that psychoanalysts and others who are psychodynamically oriented

believe psychic events to have power to create behavior or, better, that psychic events have access to, or are controlled by, a special source of power, variously spoken of as the Soul or the Ego. This source of power is . . . felt to be separate from and, in many ways, opposed to the tendencies of the biological mechanism which we call the body. They are, in other words, "obstinate dualists."

Opposed to this is the biological point of view, which is "monistic."

Bailey has no sympathy for the "obstinate dualists." He says (page 371) :

Superego, Ego and Id are only new words for the ancient dualistic manner of thinking embodied also in words, such as God, Man or Devil, which goes back at least to Zoroaster. Psychodynamicists . . . think like theologians. Having banished the Soul, they are obliged to reinstate it under the guise of the Ego, a term which they are forced to use more and more, as the theologians use the Soul.

Bailey is a learned and scholarly man whose opinions deserve close attention, but I submit that he is mistaken. I shall try to show that there is no conflict between the organic or biological view of behavior and the psychodynamic view. On the contrary, the two views are complementary. They focus attention on different aspects of behavior. There is no more conflict between them than there is between the physician who studies the clinical aspects of pneu-

monia and the scientist who studies its bacteriology.

In the study of the mind-brain problem it seems to me essential to adopt Hughlings Jackson's "doctrine of concomitance"(9). The brain is a material thing, consisting of neurones which obey the laws of physics and chemistry. How can activity of physical structures be transmuted into such immaterial things as ideas and images ? Jackson held that it is futile to try to answer this question. We can only say that a mental state is "concomitant" with activity of nerve structures. Thus, speaking of the "relation of consciousness to nervous (physical) states," he said (II, 72) :²

The doctrine I hold is : first, that states of consciousness (or, synonymously, states of mind) are utterly different from nervous states ; second, that the two things occur together—that for every mental state there is a correlative nervous state ; third, that, although the two things occur in parallelism, there is no interference of one with the other. This may be called the doctrine of Concomitance(3).

Again he said (I, 52) :

We cannot understand how any conceivable arrangement of any sort of matter can give us mental states of any kind . . . I do not trouble myself about the mode of connection between mind and matter. It is enough to assume a parallelism. That along with excitations or discharges of nervous arrangements in the cerebrum, mental states occur, I, of course, admit ; but how this is I do not inquire ; indeed, so far as clinical medicine is concerned, I do not care.

To put the matter in other words, mental states are but the epiphenomena of physical states in the brain.

I submit that if we accept Jackson's view, there is no conflict between the biologist and the psychodynamicist. As Bailey says,

¹ From the Department of Neurology and Neurosurgery, the New York Medical College, Flower and Fifth Avenue Hospitals, New York, N. Y.

² Bracketed figures refer to volume and page of "The Selected Writings of John Hughlings Jackson" (3).

the psychodynamicist believes that "psychic events (can influence) behavior," but this belief is acceptable if we understand it correctly. The influence is exerted not by the psychic events, *but by the physical states concomitant therewith.*

Material events occur only in response to material causes. They cannot be attributed to immaterial causes. But they can correctly be attributed to the material *concomitants* of immaterial (or psychic) events.

In this connection I refer to a striking passage in Tinbergen's remarkable book *The Study of Instinct* (15). Speaking of the causes of behavior, Tinbergen objects to the custom of attributing causation to "subjective" factors. Thus he says (page 4): "The conclusion that an animal hunts because it is hungry will satisfy many people at first glance." He objects to this easy explanation.

The ethologist does not want to deny the possible existence of subjective phenomena in animals (but) he claims it is futile to present them as causes, since they cannot be observed by scientific methods. Hunger, like anger, fear, and so forth, is a phenomenon that can be known only by introspection.

Tinbergen drew the right conclusion but for the wrong reason. The objection to attributing behavior to hunger is not that hunger, being a subjective state, cannot be studied objectively. Even if we had a method of studying and measuring hunger, we still could not attribute behavior to it, since behavior consists of a series of physical reactions while hunger is a mental state. Physical reactions must be explained by physical causes. Certain chemical depletions of the hungry animal arouse responses in his nervous system which manifest themselves in movements designed to correct the depletions. The function of the nervous system is self-preservation. The healthy and properly "educated" predator responds to periodic internal chemical states by finding and devouring its prey. The chemical state is the cause of the behavior. The feeling of hunger is merely an epiphenomenon.

There comes to mind an example that was one of Jackson's favorites. Jackson had an uncanny ability to spot the fallacies that may lurk behind a façade of logic. He often

referred to the motionlessness of a patient after an epileptic fit, saying that many physicians, if asked why he is motionless, would think it reasonable to answer, "Because he is unconscious." Jackson knew that you cannot attribute a physical state (motionlessness) to a mental state (unconsciousness). The correct answer, he argued, is that the highest cerebral centers (the "organ of mind") are of sensorimotor constitution (7). The unconsciousness is concomitant with paralysis of these centers, and the motionlessness with paralysis of their motor component (11). Here is one of Jackson's many statements on this matter (I, 321):

After a very severe fit of epilepsy proper, the patient does not move his limbs . . . He seems a mere breathing, circulatory, *etc.*, mechanism, lying otherwise inert on the floor. As he is then comatose, it would generally be said that he does not move *because he is unconscious*. A moment's consideration, however, will show that this is an explanation which verbally explains everything, and yet in reality explains nothing. It may pair off with such a pseudo-explanation as that a patient does not move a limb because there is loss of volition . . . It belongs to a whole family of psychologicomaterialistic confusions; it is akin to that which has it that ideas or sensations (psychical states) produce movements (physical states); to that also which declares that the mind affects the body. Nothing is said against the popular or clinical use of these expressions. No one objects in a clinical conference to the expression that . . . the mind affects the body, when it is understood that what is meant is that centres, *during activity of which mental states arise*, can affect other centres, and thus the body. But much is to be said against the use, or rather abuse, of such expressions in what purport to be scientific explanations . . . I submit that the post-epileptic comatose patient does not move, for the very simple reason that there is some negative *physical condition* of his nervous centres . . . The fact is, he cannot be unconscious without having some negative physical condition of his nervous system answering to that negative psychical condition, and it is the central negative physical condition alone (that explains) his other physical condition of immobility.

(Italics in original.)

In his third Croonian Lecture Jackson said (II, 72):

Those who accept the doctrine of concomitance do not believe that volitions, ideas and emotions produce movements or any other physical states. They would not say that an hysterical woman did not do this or that because she lacked will; that an aphasic did not speak because he had lost the memory of words; or that a comatose patient did not move because he had lost consciousness. On the contrary, they would give, or try to find, materialistic explanations of physical inabilities.

The foregoing argument would appear to support Bailey in his disagreement with the psychogeneticists. But this is not the case. Psychic events *can* influence behavior, but we must understand how this influence is exerted. We may take up the matter of learning. Experience and learning modify the brain. An Englishman and a German may each have a normal brain, yet their brains differ in their functional organization, for the article of furniture that you sit on causes one to think of the word "chair" while the other thinks of "Stuhl." These two words presuppose different patterns of innervation of muscles of articulation. Learning has caused these men to respond differently, with different patterns of tongue and lip movement, to the same stimulus.

The psychodynamicist is more particularly concerned with the effects of *emotional* experience. He believes that emotional experience in childhood can leave its stamp on later patterns of behavior. This belief cannot be disputed. If a child is frightened by a dog, his behavior may show it for years afterward. The psychodynamicist cannot be criticized for such a belief. He can be criticized only if he denies that the influence of psychic events is mediated by cerebral mechanisms.

The biological and the psychodynamic points of view are both necessary if we are to understand behavior. We must study psychodynamics to understand why we are what we are, why we behave and think as we do. We must study brain function to understand the cerebral mechanisms that mediate psychodynamic influences.

The man who has done the clearest thinking on the mind-brain problem was Hughlings Jackson. Being interested in the manifestations of brain disease, he paid close attention to the mental disturbances seen in

epilepsy and other organic and toxic states. He made some remarkable observations in toxic delirium. Thus he showed that the delirious patient tends to mistake the unfamiliar for the familiar (as when he mistakes the nurse for his wife) and this error of orientation is a manifestation of "reduction to a more automatic condition" (6). He had the useful habit of looking for similarities between complex phenomena, such as mental symptoms, and simpler disturbances from disease of lower levels, it being a favorite thesis of his that higher and lower levels of the nervous system, though they differ enormously in complexity, are fundamentally alike and obey the same physiological laws.

Jackson, whom Otto Sittig once called the profoundest thinker in the history of neurology, has charted a path that we might follow with profit. To give but one example, the delirious patient, being disoriented, may be unable to answer correctly when you ask him to name your occupation, yet in spontaneous conversation he may address you as "Doctor," as when he says "Good morning, Doctor" or "Thank you, Doctor." There have been instances in which the patient addressed me as "Doctor" *in the very sentence* in which he misnamed my occupation. Thus a patient in a bromide delirium, when asked to name my occupation, replied, "I wouldn't know, Doctor—is it painting and decorating?"

But this phenomenon ceases to be puzzling when we consider that it is exactly parallel to one seen in aphasia. The aphasic, as Jackson often pointed out, can sometimes say a word spontaneously which he cannot say on command. Thus if he cannot say "No" when you ask him to, he may say it in reply to a question calling for a negative. The parallel even extends to those instances in which the delirious patient addresses you as "Doctor" in the very sentence in which he misnames your occupation. Thus an aphasic, after a vain effort to say "Pencil" on command, may give up in despair and cry out, "No, I can't say pencil."

Here is a precise parallel between a "mental" symptom, disorientation, and a disturbance seen in organic disease, aphasia. The significance of the parallel has been discussed elsewhere (5; 8). The two phenom-

ena are manifestations of the same physiological principle, "reduction to a more automatic condition." We see here the profit to be gained from viewing a mental phenomenon from the biological viewpoint, as a manifestation of a disturbance in cerebral physiology.

MONISM AND DUALISM

Bailey regards the psychodynamicists as dualists, and once again I take issue with him. This is not an easy matter to discuss, for there are many definitions of monism and dualism, and as an amateur in the province of philosophy I "stick my neck out" with apologies.

In the study of neurology the monist, it seems to me, is he who believes that all behavior (including mentation, which is internal or subjective behavior) can and must be accounted for on the basis of cerebral activity, psychic activity being but the concomitant, or epiphenomenon, of cerebral activity. The dualist, by contrast, is he who believes that brain activity cannot explain all of behavior and who assumes a "soul" that is higher than the merely material brain.

To discuss this matter in more specific terms, I quote a comment by Schiller (14) in reference to Hughlings Jackson. Schiller said, "His was the Cartesian dualism of mind and brain, the brain being merely the organ of mind." But I submit that Jackson's formulation makes him a monist, not a dualist. A strict materialist, he regarded mental activity as a manifestation of activity of the highest cerebral centers (the "organ of mind"), even though, in keeping with the doctrine of concomitance, he maintained that the transmutation of physical into mental will ever remain a mystery.

Walshe too seems to have made the same error. In his review of Lord Cohen's book on Sherrington (16), Walshe, referring to Sherrington's comment on the unsolved mystery of the mind-brain relationship, has this to say:

But surely, this negative attitude, which was that of Hughlings Jackson also, is not "a philosophy." It is simply an honest admission of a problem for which, as they thought, natural science did not provide the solution. Both were dualists in a negative sense.

As to Sherrington, Walshe's judgment appears to be another example of a correct conclusion based on the wrong reason. Sherrington was indeed a dualist, but not because he accepted the insolubility of the mind-brain relationship. His conversation with Brain (2) suggests that the dualistic position appealed to him. As to Jackson, Walshe's designation of him as a dualist is in my opinion a mistake, for reasons already given.

A good example of the position of the dualist is found in the writings of Thomas Laycock (the man whom Jackson credited with the thesis that the highest cerebral centers obey the laws of reflex action). Laycock (4) quoted with approval Morell who said that the soul exists "prior to consciousness," since it exists "from the formation of the first cell-germ" (vol. I, p. 129). On page 283, after saying that man stands at the head of an ascending scale of animal life, Laycock argued that the scale is

not truncated at man, and that beyond him there cannot be a dark, unpeopled void . . . (There is) an infinite gradation of Being, above and superior to man. That we cannot see such Beings, nor demonstrate their existence, is a necessary result of our position in the scale, and no proof whatever of their non-existence. The worm knows nothing of man, his works, or his actions; nothing of the sun or the stars . . . ; and so, with reference to the spiritual world—the world around and above us—our organs may be as imperfect as those of the worm with reference to the world around and above it.

Bailey prefers monism to dualism. Penfield (13) quotes Lord Cohen that "the ultimate goal of science is a universal monism." But Penfield himself seems to waver. Speaking of the "master mechanism" which he postulates in the brain stem, Penfield says:

What is the real relationship of this mechanism to the mind? Perhaps we will always be forced to conjure up a spiritual element of different essence situated between the sensory complex and the motor machine, a spiritual element that is capable of controlling the mechanism.

But though we may sympathize with Bailey in his preference for monism, we need not accept his criticism of the psycho-

dynamicist as an "obstinate dualist." The psychodynamicist is a monist so long as he believes that mental and emotional experience affects cerebral processes, and that only thus can we account for its influence on behavior.

There is no contradiction between the psychodynamic and the organic points of view. They both help us to understand behavior. Just as the world needs both the artist and the scientist, and medicine needs both the clinician and the physiologist, so does the study of behavior require the collaboration of the psychodynamicist (psychiatrist, psychoanalyst) and the neurologist.

DIFFERENTIATING VARIABLES : OBSSIVE-COMPULSIVE NEUROSIS AND ANOREXIA NERVOSA

JOHN CLANCY, M.B., B.Ch., AND ALBERT NORRIS, M.D.¹

There has been considerable disagreement among psychiatrists in the diagnosis of anorexia nervosa. In 1874, Sir William Gull (3) described the condition which was characterized by "repugnance of food, extreme emaciation, amenorrhoea and personality changes." A review of the literature indicates that while most authors accept the aforementioned as definitive symptoms, there is much disagreement as to the nature of the condition, the type of personality and emotional conflict with which it may be associated, and method of treatment. It would appear that the clinician's interpretation and evaluation of these latter items also influences his diagnosis of anorexia nervosa.

Anorexia, loss of weight and amenorrhoea may be observed in many psychiatric illnesses, and it is not surprising that the condition should be considered as a depression or schizophrenia. Eissler (2) suggested that there were 3 degrees of anorexia nervosa : it could be symptomatic of hysteria, schizophrenia or melancholia, it was a disease entity in itself, and a third group fell between these divisions. However, most authors are concerned with the close similarity between anorexia nervosa and obsessive-compulsive neurosis. DuBois (1) concluded that "anorexia nervosa is fundamentally a compulsive neurosis with cachexia as a leading symptom." Rahman, *et al.* (5) in a study of 12 cases of anorexia nervosa believed it to be a neurosis with obsessive-compulsive features. On the other hand, Kay and Leigh (4) in a very complete study of 38 cases of anorexia, while impressed with the frequency of obsessional traits in the personalities of these patients, concluded that there was no neurosis specific to anorexia nervosa. Neither were they convinced that anorexia nervosa is a psychiatric entity.

Recently we observed 2 young female patients who were diagnosed by competent psychiatrists as suffering from obsessive-

compulsive neuroses. It was noted at the time that both patients presented the definitive symptoms of anorexia nervosa as described by Sir William Gull, in addition to obsessive-compulsive features. Further inquiry disclosed many other similarities in their symptomatology, personality, onset and course of illness, life history and family history. It was soon recognized that most of these items which were common to both patients' profiles were frequently found in the profiles of patients suffering from either anorexia nervosa or obsessive-compulsive neurosis. Certain features present in both patients, however, could not be considered characteristic of either anorexia nervosa or obsessive-compulsive neurosis. Just prior to the onset of avoidance of food and weight loss, a variety of psychiatric symptoms appeared in both patients, which disappeared when the final clinical picture became established. These transient symptoms we have labelled "premonitory trial symptoms." Peculiar to both patients were periods during which there was a greatly increased intake of food interspersed with greatly diminished intake. This "cycling" in food intake tended to persist through the course of the illness. A poor phantasy life and a definite history of allergic and psychosomatic disturbances in earlier life were other common features not typically though occasionally seen in cases of either anorexia or obsessive-compulsive neuroses. Since these patients have been diagnosed as obsessive-compulsive neurotics, we asked ourselves the following questions :

1. Can a clinical distinction be made between anorexia nervosa and obsessive-compulsive neurosis? If such a distinction can be made,

2. What features of these conditions serve to differentiate them?

3. Is it possible that both conditions can coexist in the same patient as suspected in the 2 special cases under study?

In an effort to find an answer to these questions, we have used the following method of comparison.

¹ From the Department of Psychiatry, Psychopathic Hospital, State University of Iowa, Iowa City, Iowa.

METHODOLOGY

Variables in the family history, life history, personality and symptomatology common to both of these patients were listed. Further variables considered to be characteristic or frequently found in the profiles of anorexia nervosa or compulsive neurotics were added to make a total of 22 variables. The hospital records of 8 anorexia nervosa patients and 10 obsessive-compulsive neurotics, who had been diagnosed as such by independent psychiatrists, were then obtained. The patients were matched for sex and as close as possible for age. The list of variables in Table 1 was compared on each case history.

In order to test the significant difference in the occurrence of these variables in anorexia nervosa and obsessive-compulsive neurosis, the Fisher test(6) of exact probability was applied. This is a nonparametric technique for analyzing discrete data when the 2 independent samples are of small size.

RESULTS

To a significant degree certain variables occurred more frequently in anorexia nervosa than obsessive-compulsive neurosis. Those patients diagnosed as suffering from

anorexia nervosa were distinguished by the presence of a history of neurotic traits in childhood, a conflict associated with school, excessive activity during the period of illness, amenorrhoea, anorexia and weight loss. In the sample under study, the anorexia nervosa patients demonstrated on the average 5 of the 6 aforementioned significant variables. In no instance were there fewer than 4 of these variables present. On the other hand, only once did any of these variables significant for anorexia nervosa appear in the profiles of an obsessive-compulsive neurotic.

The obsessive-compulsive patients could be distinguished from the anorexia patients by the presence of compulsive acts, obsessive thinking, a poor phantasy life, concern about symptoms, and an interruption of their accustomed activities. The obsessive patients demonstrated on the average 3.7 of the 5 variables significant for that condition. In no instance were there fewer than 3 present. In comparison the anorexia patients averaged only 1.4 of the variables significant in obsessive-compulsive neurosis.

When both sets of significant variables were applied to the case histories of the 2 special cases under consideration, we found that these patients showed a sufficient num-

(22) Catholic religion	4	5	n.s.

ber of each set to warrant a diagnosis of both anorexia nervosa and obsessive-compulsive neurosis.

DISCUSSION

In attempting to make a clinical differentiation between anorexia nervosa and obsessive-compulsive neurosis, we have found significant differences in the occurrence of certain variables which tend to distinguish them as clinical entities. We have also found that these conditions can coexist in a patient. In addition, these 2 conditions have many features which traditionally have been used to differentiate them, but in fact are not statistically reliable in making a differential diagnosis.

In neither group was there found evidence of undue obsessive or meticulous traits in the parents of these patients. While the patients tended to be obedient, "model or good" children with a need for success at school, these characteristics did not distinguish them from each other. Perfectionistic and meticulous traits were as common in the personalities of anorexia nervosa patients as in the personalities of the obsessive-compulsive neurotics. Patients of each group were lacking in ability to make close and lasting friendships with their peers. Psychoanalysts have sought for the roots of obsessive-compulsive neuroses in parental relationships during the anal stage of libidinal development and have formulated the dynamics of this neurosis around the conflicts of this developmental stage. In our sample, a history of early punitive, or difficulty in, toilet training was notably infrequent in both the obsessive and anorexia patients. While a conflict in respect to sex, or an unhealthy attitude towards sex, seemed to be the rule rather than the exception, there appeared to be no specific type of conflict peculiar to either diagnostic category.

CONCLUSIONS

Anorexia nervosa and obsessive-compulsive neurosis have many features in common. It would appear, however, that they are capable of being distinguished from each other on a clinical evaluation of the history, personality and symptomatology of the individual patient. Amenorrhoea, anorexia, loss of weight, excessive activity during the period of illness, a conflict associated with or reflected in school adjustment, and a history of neurotic traits in childhood are characteristic of anorexia nervosa. Compulsive acts, obsessive thinking, a poor phantasy life, concern about symptoms and an interruption of accustomed activities are more liable to be associated with obsessive-compulsive neurosis.

The 2 conditions can exist together in a patient, and in this instance the diagnosis should be so stated.

SUMMARY

The records of patients with the diagnosis of anorexia nervosa and obsessive-compulsive neurosis were examined with respect to certain variables. These were compared with 2 patients who had features of both conditions. The results are described.

PROCESS, SCHIZOPHRENIC AND THERAPEUTIC : SOME MISCONCEPTIONS RESULTING FROM LANGUAGE AND PHILOSOPHY ¹

EDWARD S. DEAN, M.D.²

In psychiatric discussions the term *process* is frequently misused. It is misused because of preconceptions rooted in our language and because of a tradition of thinking in essences. Thinking in essences results in misunderstanding and poor treatment.

Psychiatrists can improve their theory and practice by identifying and rejecting preconceptions based on essences. What is needed is a phenomenal approach, as for instance in the theory and treatment of schizophrenia.

THE CONCEPT OF ESSENCE

What I mean by thinking in essences is the tendency to assume that everything has an inner and higher reality that determines its external characteristics. The essence of a thing, it is believed, is that which determines its nature.

As applied to people, the term refers to an inner quality that determines character. An essence approach assumes an inner nature that shows itself in traits of character. For example, a person who acts dishonestly will be considered dishonest by nature. His dishonest behavior will be regarded as determined by the essence of dishonesty. Thus the quality assigned to an act is transferred to an assumed inner nature.

The essence concept goes back to Plato, the classic philosopher, with his supra-sensory world of ideas apprehended by reason and intuition. The Platonic ideas are qualities in pure form. The good, the true, and the beautiful are such because they partake of the idea, or form, of goodness, truth, or beauty. Likewise, dishonesty partakes of the quality of dishonesty. This quality is eternal and exists in pure form somewhere in a realm beyond the reach of our senses.

In short, an essence is a metaphysical concept. It has no tangible existence. The medieval philosophers reduced the concept of essence to an element in definition. They held that an essence is that characteristic without which a thing loses its identity.

Modern philosophy has had less use for the term. But the concept persists in our language and thought with its original vitality. It dominates what is called common sense. Inevitably, it has found its way into psychotherapy.

THE INFLUENCE OF LANGUAGE

A further consideration is that the tendency to think in essences is encouraged, if not enforced, by the structure of our language.

Naming : First of all, we give names to concepts, and names tend to promote the assumption that what is named has objective existence. This is like the tendency to believe a thing is true because one sees it in print. Like the printed word, names are loaded with an authority which may be wholly illusory.

John Stuart Mill(1) said :

The tendency has always been strong to believe that whatever receives a name must be an entity or being, having an independent existence of its own : and if no real entity answering to the name could be found, men did not for that reason suppose that none existed, but imagined that it was something peculiarly abstruse and mysterious, too high to be an object of sense.

One may decide that a man who does not work is lazy. Having found a name for this behavior, one tends to assume that laziness is real and exists of itself, that it is an essence affecting certain individuals. Such is the customary view of laziness.

But Sir Heneage Ogilvie(2), the prominent British surgeon, has a different view. He says, "Laziness implies a lot of intelligence and it is the normal, healthy attitude

¹ Presented July 31, 1960 to the International Conference on General Semantics at Honolulu.

² 450 Sutter St., San Francisco 8, Calif.

of a man with nothing to do. Its great enemy is conscience—the fear of disapproval.”

So it is seen that laziness is merely a judgment pronounced on behavior. The only actuality is the behavior and one's attitude toward it. Laziness has no existence apart from the thinking of human beings.

Thus the names we give to concepts tend to enforce the habit of thinking in essences.

Suggestion : In the second place, names given to concepts have acquired strong charges of value, positive or negative, so that these names have a powerful effect on our attitudes and feelings. For example, if you tell a woman in good health that she is not looking well, she begins to feel unwell. Tell her that she is lovely, and she reacts accordingly.

This power of “word suggestion” is felt not only by the person named but also by the one who names. A woman becomes more beautiful to the man who thinks her lovely. If he thought, “She's not good-looking,” she would lose attractiveness in his eyes.

Thus to both subject and object words bring about important changes in attitude. This effect makes us feel that some essence called up by our words is really there, intangible and ineluctable, controlling our destiny. So it is that the values assigned to words reinforce the belief in essences.

Objectification : Language exerts still another pressure toward thinking in essences, because words, by suggestion, connotation, and metaphor, evoke the image of a physical object, capable of being seen and felt. For instance, we speak of someone as being hard, or soft, or smooth, or dull, or brilliant. Each of these is a metaphorical term suggesting a physical object.

Benjamin Lee Whorf(3) stressed this tendency of our language to designate abstractions by words suggesting physical objects. And he showed that some languages work in an opposite manner. European languages tend to *objectify*, that is, to treat an event as if it were a physical object. We objectify time when we speak of 10 days—or the events we call 10 days—as an aggregate seen at one time, like 10 men. But the Hopi Indians have a language

which refers to a world of *event*. They think of time as “getting later.”

Whorf says we carry about with us an imaginary space into which we project mental images. But the Hopi believe that the thought of an object, say a tree, goes out to that actual, existing tree. They do not conceive of thinking with mental images.

While the Hopi language stresses event, or what happens, European languages objectify, call up mental images. And these images bear a family resemblance to the Platonic forms, or ideas. Thus the tendency of our language toward objectification disposes to the belief in essences.

ESSENCE AND CHARACTER

The belief in essences leads to an essence view of character traits, and this does violence to the person in question. For a man convicted of an essence is denied appeal from this judgment. Such a finding puts an end to inquiry, preventing further questions.

In the case of the man who will not work, the finding of laziness, under the essence view, may satisfy the need for understanding, but the individual may be seriously misunderstood. He may appear lazy because he dreads revealing himself in action : he fears he will be found incompetent. Now a remedy for his “laziness” presents itself : he needs the training and experience necessary to assure him of his competence.

So if we discard the essence view, new avenues become available for exploration. We find that character traits depend upon a particular course of life and a particular attitude of mind, and this leads to typical decisions.

The man who seemed to be lazy may have had a childhood experience of excessive criticism from his parents. They may have expected too much from him at too early an age. He could never please them, and he came to have an abiding lack of confidence in himself. He feared revealing his incompetence, real or fancied, because he expected that his effort would be met by a chorus of disapproval. Thus are character traits developed, the so-called ingrained qualities of our nature.

ESSENCE AND SCHIZOPHRENIA

The concept of essence is a source of confusion not only with respect to character traits, but also with respect to the more extreme states of mind, such as the schizophrenic psychosis.

There is a strong tendency to assume that schizophrenia results from the working of some kind of inner essence. This remains true even when a term such as *process* of schizophrenia is employed. For in using this term one is inclined to accept the analogy of a seed that germinates, develops, and reaches full flower. In fact, some psychiatrists look upon schizophrenia as if it really were the result of a seed implanted in the person early in life or acquired hereditarily through the genes. Further, there is a feeling that the person who merely harbors the "seed" of schizophrenia is faced with a dreadful future, because of the process of the disease. The seed may germinate, feed upon its host, and destroy him.

Also, there is a belief that schizophrenia may exist in a latent form which at any time could break forth and take possession of the person, causing him to cease to be himself and to become psychotic. In this respect, psychiatry is under the influence of a demonology right out of the Dark Ages. For a man possessed by a process is not greatly different from a man possessed by a demon.

Under the influence of the essence view, one is inclined to accept the gloomy prognosis assigned to schizophrenia, to accept as sufficient evidence of a poor prognosis those patients who spend their lives in hospitals, bizarre in their conduct and withdrawn from human fellowship. But if we examine all the manifestations called schizophrenic, this poor prognosis is not confirmed by the facts.

Most psychiatrists engaged in hospital work have noticed an occasional patient admitted in a disturbed, delusional state, within a few days become apparently normal without benefit of treatment. In an office practice devoted to psychotherapy, it is not unusual to encounter a patient who in the first interview pours out enough delusional material to make hospitalization seem necessary. But in subsequent interviews he talks about fairly ordinary life

problems, and his fantastic delusions shrink into the background. Then there is the patient who recounts an episode from his distant past in which he was clearly psychotic, if only for an hour or so, but who then goes on to lead a life that is not otherwise unusual.

Often when an expert in the treatment of schizophrenia, such as Harry Stack Sullivan, is with a person who is schizophrenic, that person ceases to act in ways commonly known to be schizophrenic. For that time, at least, he is no longer schizophrenic.

All this suggests that schizophrenia is not an essence, but that it is *phenomenal*. It is the way a person may be in certain conditions of life. Given the right circumstances, just about anyone could be schizophrenic.

But the essence view of schizophrenia leads to misunderstanding, and it burdens the psychiatrist, as therapist, with a sense of futility and impotence. He regards the schizophrenic person as if he were the passive victim of a metaphysical process. This vision of an intangible and inaccessible entity leads to therapeutic despair and makes destructive methods of treatment, such as electric shock, insulin, and lobotomy, seem reasonable.

ESSENCE AND PSYCHOTHERAPY

Not only an essence view of *disease process*, but also an essence view of *treatment process*, may be a source of difficulty for a therapist. For he may be tempted to rest secure in what he conceives as the process of treatment. He thinks of such a process as having an objective existence, although somewhat mystical in nature, as if there were some vaguely defined entity of considerable power to which he might turn for help. By proper propitiatory gestures he can summon it up, control it, and make it work for him.

But have a care. This "entity," like a genie, may take offense and desert the effort just when a good start has been made. The good genie has a jealous nature and seems to be distinctly resentful of those therapists who are given to self-congratulation. For with attention focused upon the operation of metaphysical entities, a therapist can ignore real human events. He may fail to appraise properly the mute, dis-

sembling appeal of the person regarded as schizophrenic. (He may say that he hates you. He thinks you are a disguised Communist. He hopes you are not. He hopes you are his friend.) This lack of sensitivity and understanding is due to the mistaken feeling of confidence in what one "knows" about the schizophrenic process: the "withdrawal from contact," the "inability to form a relationship," and the "predominance of the primary process."

Concentrating upon the elements of an essence process, the therapist seeks to manipulate these abstractions in a way that is favorable to the process as it is conceived. For example, from theory, the opinion is deduced that a patient is in danger of developing a psychosis—a possibility that may be purely theoretical. So an attempt is made to forestall such a development by "strengthening the defenses." Thus preoccupied, one fails to notice when the patient is offended by statements intended to be therapeutic, because one is out of tune with him. Distracted by theory, these disharmonies are accounted for by relating them to "resistance," or "transference phenomena," or "not ready for therapy."

The elements of this theoretical process are nothing more than concepts which have been endowed with a metaphysical reality and a vital force. Reliance on such theory may lead to poor treatment.

What is needed is a clear recognition of the harm done to psychiatric thinking by acceptance of the essence concept. A close examination of the concept will result in its rejection, particularly as applied to a process of disease and treatment. Then reason will be found for making a clear distinction between an essence process and a phenomenal process. For a process is not an entity; it is merely a course of events.

THE PHENOMENAL POINT OF VIEW

The approach that I have found useful has antecedents in phenomenology. By this I mean simply the description of actual phenomena, avoiding all interpretation, explanation, and evaluation.

Such a point of view was first proposed in 1894 by Wilhelm Dilthey(4), the German philosopher, who wrote that

... the aim of psychology cannot be an explanation: for every explanation tries to reduce into elements; this aim is rather a *description*: ... a faithful narrative of what is seen as a whole direct by man himself. ... We contemplate ... with an understanding look.

In 1913 Karl Jaspers(4) reported the application of this point of view in psychotherapy. His method depends upon

... the completest and most careful description possible ... of what is experienced by healthy or by sick people, ... an exposition of what comes to show itself to us ... with imperative clarity. This ... is always a susceptible understanding: ... the inner self of another is never given to us direct: we try to enter into another's life and ask ourselves what we feel. ... Ultimately ... all phenomenology depends on introspection.

Jaspers opposed an "understanding" approach to a causal approach. But the causal approach has been dominant in psychotherapy. Sigmund Freud was always intensely interested in explaining mental phenomena. Yet he developed a method of treatment in which, as a necessary result of "free association," a full and complete description of the patient's experience occurs. Perhaps Freud, in his emphasis on interpretation, neglected an important source of the favorable change that does occur in psychoanalysis.

In America the foremost exponent of a phenomenal point of view is Carl R. Rogers. He apparently arrived at his position independently of the European phenomenologists. But a similarity to Jaspers is evident, to some extent, in the following:

Every individual exists in a continually changing world of experience of which he is the center. This private world may be called the phenomenal field, the experiential field, or described in other terms. ... Only a portion of that experience ... is consciously experienced. ... This private world ... can only be known, in any genuine or complete sense, to the individual himself. ... My actual awareness of and knowledge of my total phenomenal field is limited. It is still true, however, that potentially I am the only one who can know it in its completeness. ... Behavior might be best understood by ... seeing the

world of experience as nearly as possible through (the individual's) eyes(5).

In Rogers' view, therapeutic

change appears to come about through *experience in a relationship*. . . . Thus the relationship which I have found helpful is characterized by a sort of transparency on my part, in which my real feelings are evident ; by an acceptance of this other person as a separate person with value in his own right ; and by a deep empathic understanding which enables me to see his private world through his eyes. When these conditions are achieved, I become a companion to my client, accompanying him in the frightening search for himself, which he now feels free to undertake(6).

CONCLUSION

The task of the therapist, then, is a close attention to the experience of his patient, but *not* interpretation, explanation, or evaluation. What is needed for good treatment is that the therapist be "tuned in" on his patient, receive him clearly, and let him

know that he is understood. If he keeps close to the phenomenal, the psychiatrist can avoid the hazard of thinking in essences.

CLINICAL NOTES

(The Clinical Notes report the findings of the authors and do not necessarily represent the opinions of the Journal.)

INCREASED CONTROL OF INSULIN COMA BY PRIOR ADMINISTRATION OF GLUCAGON : A PRELIMINARY COMMUNICATION ¹

KARL T. DUSSIK, M.D.,² DONALD B. GIDDON, D.M.D.,³
PETER D. WATSON, B.S.,⁴ AND JOEL J. WHITE, M.D.⁵

The hyperglycemic-glycogenolytic factor, Glucagon(1, 5), has been used extensively in our hospital(10) and elsewhere as an additional agent(2, 7, 8, 9) in Insulin Coma Therapy for rousing patients from deep coma so that they can swallow a sugar solution. Glucagon is thought to act by producing a transitory hyperglycemia due to its glycogenolytic action on the liver glycogen.

One of us (KTD) assumed that perhaps the administration of Glucagon before the insulin might reduce both the amount of insulin needed to produce coma as well as the time of onset of the coma itself. If this were found to be true, not only would it shorten the treatment time but it would also reduce some of the risks of ICT, as there is evidence that smaller doses of insulin are associated with fewer side and/or after-effects. A shorter phase 1 (during which time daily increasing doses of insulin

are given until coma ensues) is preferable because, in general, it is recognized that a decided improvement of the psychotic symptoms starts once comas are reached. It was also felt that such a procedure might be effective in producing a coma in previously coma-resistant schizophrenics.

A technique was thereby devised where 0.5 cc. of Glucagon was administered I.M. 4 hours prior to the insulin, *i.e.*, at 3:00 a.m. and 7:00 a.m., respectively. (Experiences after the period reported here show that it is preferable to use 1.0 cc. of Glucagon at 3 a.m.) This seemed a reasonable time to allow for the depletion of the liver glycogen stores and the return of the level of the blood-sugar in the venous blood to normoglycemic values.

This technique was clinically evaluated in two ways. One group of 11 patients, who were already in ICT and for whom coma doses of insulin had already been established, was switched to the Glucagon-insulin regime described, thus serving as its own control. A second group of 19 patients was started with the Glucagon-insulin treatment and compared with an earlier group of 179 patients who had been treated with insulin alone, either with single or multiple doses, excluding 30 patients treated by the Shurley-Bond technique.

Table 1 compares the established coma doses in the 11 patients of group 1 before we started to give Glucagon at 3 a.m. and after this technique had been started. Note that in all 11 cases use of Glucagon lowered the amount of insulin necessary to produce comas of equal depth. This held true whether one had used the Classical technique, the Shurley-Bond technique, or the Laqueur

technique for the day to day increase until the first coma had occurred. These changes are statistically significant by the non-parametric sign test (p less than .001).

Although it is unlikely that time alone—without added Glucagon—could account for this phenomenon, one should compare these changes in patients who remain on insulin alone over similar time periods.

Table 2 presents both the insulin coma dose and the number of days before the occurrence of the first coma for the 19 patients who started ICT with the pre-treatment use of Glucagon. Note that only the Classical and Laqueur techniques are employed here

because of the possibility of dangerous over-dosage if the Shurley-Bond technique were used in cases receiving Glucagon prior to insulin.

These data are compared with a previous group of 179 patients treated with insulin alone (see Table 3). Statistical analysis(3) reveals that both the mean of the dosage and the mean of the number of days to reach the first coma are significantly lower in the Glucagon group. Furthermore, the variability (F ratio) of the Glucagon group is also significantly less than that of the group treated with insulin alone.

In addition to the obvious importance of

TABLE 3
COMA DOSE REQUIRED FOR FIRST COMA

** p less than .01.

the decrease in average dosage and the number of days to reach the first coma for the Glucagon-insulin form of treatment, the reduction in the variance of the dosage needed with this technique may have considerable clinical significance. This means that treatment with the Glucagon-insulin regime is more uniform, thus providing better control over the therapeutic situation.

So far, no untoward effects of Glucagon have been observed either when it was used to arouse patients from coma or in any of the 30 cases reported here. No differences in the course of coma were noted except for possibly a slight deepening in a few instances. Presently, 360 comas have been produced with Glucagon in the 19 patients of the second series, several of which are still under ICT. The daily preadministration of Glucagon tends to progressively reduce the amount of insulin needed to reach coma. In 2 patients, the doses required to produce coma after Glucagon could be reduced to as little as 25 units of insulin, one after a single injection, the other after multiple doses (after tabulation of Table 2). The reduction in insulin requirement, after Glucagon, should, therefore, be carefully gauged in the same ways as in ICT without preceding Glucagon: If coma begins before the end of the second hour and seems too deep, the dosage of the next day is reduced by 10 or more

units of insulin, but if the coma starts too late or is too mild, then an increase in dosage is given the next day.

It should be noted that Glucagon could safely be used to rouse the same patients from coma who were pre-treated with the hyperglycemic-glycogenolytic factor before insulin. It is probable that this arousal dose of Glucagon acts on glycogen reserves rebuilt by glyconeogenesis during the coma.

Secondary reactions are rarer and less severe in this Glucagon-treated group than had previously been observed in the cases not pre-treated with Glucagon. In one instance a patient became somnolent around 7:00 a.m. before she had received insulin, and the insulin was omitted for that day. In this case, it was possible to administer another dose of Glucagon on the following day successfully. (This patient was released after 62 comas without further unusual responses, and with a remission corresponding to a Grade 2 result(11).)

The effect of Glucagon administration on the C.N.S. appears to be different from that of hyperglycemia due to ingestion or injection of carbohydrates. Some observations point to the possibility that, because of the rebound of the regulation of carbohydrate metabolism, effects of Glucagon administration could be used to somewhat approximate the effects of subcoma insulin treatment.

CONCLUSIONS

We believe that the use of Glucagon for the arousal of patients from insulin coma and as a facilitating agent in the induction of insulin coma constitutes an important development in the modern treatment of schizophrenic psychoses, since it seems to render Sakel's treatment much easier to administer and contributes to its safety and economy.

EFFECTS OF CHLORDIAZEPOXIDE IN SEVERELY DISTURBED OUTPATIENTS

FELIX BAMBACE, M.D.¹

A series of 73 clinic patients, of whom roughly two-thirds were diagnosed as schizophrenics or as exhibiting psychotic symptoms, responded well to therapy with chlordiazepoxide (Librium)² in a study extending over a 6-months' period. This clinic acts as clearing house for the San Antonio State Hospital, screening new patients and taking over the care of others discharged from the hospital or on furlough during periods of remission. Our heavy work load makes it impossible to see patients at frequent intervals on an individual basis, and we have relied heavily on drug therapy.

Because of the large proportion of chronic and severe cases seen in this clinic the phenothiazines in variety have been the drugs of choice, despite their unpredictability and their tendency to produce side effects. In some cases these agents have apparently shortened periods of remission; more often they have failed to reduce anxiety and control undesirable behavior.

Reports of the high safety index of Librium and its specific action on anxiety led us to make the present study.

The population consisted of 31 males and 42 females, age range 16 to 73 years. The diagnoses included schizophrenic reactions 25 patients, psychoneurotic reactions 21, personality disorder 7, anxiety reaction 7, and affective reaction 5. The disturbance was often of long standing; 29 of the group had been hospitalized previously, often several times, and others had been under psychiatric treatment for many years.

The general run of patients were given Librium, 10 mg. b.i.d., or more often, t.i.d., and this amount proved acceptable as a maintenance dose in many cases. Duration of treatment ranged up to 6 months.

Seven patients were lost to follow-up. Of the 66 remaining cases, 39 were rated as showing excellent response; in 11 the results were good, in 4 fair, and in 6 poor. In 6 patients, hospitalized for electroshock therapy, no evaluation of Librium was attempted.

Thus 50 patients (75.7%) obtained good or excellent results from Librium medica-

¹ Director, San Antonio State Adult Mental Health Clinic.

² Trademark of Hoffmann-La Roche Inc., Nutley, N. J.

tion, and the alleviation or remission of symptoms was predominantly, rather than moderately, marked. The best response was in the psychoneurotic group (17 of 21), cases of anxiety reaction (6 of 7), and the 2 mentally deficient patients. However, the results in the schizophrenic group of 25 were especially noteworthy: 11 showed an excellent response and 4 a good response (60%). Of the 5 paranoid type schizophrenics 2 received some benefit, but the other 3 were hospitalized when Librium failed to control their symptoms. The drug was also of little value in the 2 manic-depressive patients.

Unless the patient was suffering organic brain deterioration, grave endogenous depression or a marked cyclothymic illness, Librium exerted what might be called a benign effect: obtunding of anxiety, phobias, obsessive thinking and compulsive behavior and initiating a more normal level of thought and action. Especially valuable was the psychostimulating action of Librium which enabled many patients to accept inevitable life situations and others to take positive steps toward recovery by joining group therapy and vocational rehabilitation programs.

A minimum of side effects was noted; 4 patients reported drowsiness and slight ataxia, 3 became nervous or overstimulated. These effects were reversed when Librium dosage was reduced, except in 2 schizophrenics.

SUMMARY

Of 73 outpatients with predominantly psychotic diagnoses the results of Librium therapy were excellent in 39 and good in 11. The drug relieved symptoms of anxiety, phobias, obsessive thinking and compulsive behavior, exogenous depressions, and conversion reactions. Librium was less effective in manic-depression, psychotic depressions and paranoid-type schizophrenia. Slight and transient side effects, mainly drowsiness and ataxia, occurred in a few cases. Patients with a long history of illness and hospitalization, who had not responded to previous medication with one or several of the phenothiazines, showed marked improvement under Librium therapy.

LONG-TERM RESULTS OF FRONTAL LOBOTOMY IN SCHIZOPHRENIC PATIENTS

JANE E. OLTMAN, M.D., AND SAMUEL FRIEDMAN, M.D.¹

This is a brief summary of results achieved in a series of schizophrenic patients who underwent a standard, closed frontal lobotomy operation during the period May, 1946 to December, 1950. The status of these patients on January 1, 1961 was recorded. Thus a period of approximately 10 to 15 years has elapsed since operation. Re-

sults in the operative group were also compared with those in a control group of patients, previously described (1), who had been approved clinically for the procedure but for whom operative permission had been refused. Progress reports were obtained by various methods on patients who were no longer hospitalized at this institution. They included direct telephonic inquiries, examination at outpatient clinic, reports from other hospitals, correspondence

¹ Respectively, the Clinical Director and the Asst. Superintendent, Fairfield State Hospital, Newtown, Conn.

TABLE 1
Status of Lobotomized and Control Patients

GROUP	TOTAL NO.	OUT OF HOSPITAL NO. - %	DECEASED NO. - %	HOSPITALIZED NO. - %
Operative group	200	50 - 25%	22 - 11%	128 - 64%
Control group	63	2 - 3%	11 - 17%	50 - 80%

and social service inquiries. Only one patient was lost from view. There were 200 patients in the lobotomy group and 63 in the control group with satisfactory follow-up information.

The current status of these patients is summarized in Table 1.

It is apparent that results in the lobotomy group, although limited, are definitely superior to those in the control group. The difference is statistically significant ($p < .001$).

It is pertinent to note that the death rate in the operative group is actually less than in the control group, indicating that the operation does not cause a specific increase in mortality rate during succeeding years. It might be indicated further that 2 of the deaths were associated with the occurrence of a convulsive seizure; the remainder were due to a variety of conditions not apparently associated with the original operation. In the control group, 3 of the deaths were due to pulmonary tuberculosis, all occurring before 1949. Although the problem is now much less pertinent, it may be noted that we have previously (2) commented on the beneficial effect of frontal lobotomy on tuberculous schizophrenic patients.

The very limited number of control patients currently out of the hospital again confirms the long accepted viewpoint that schizophrenia is characteristically a chronic disease and that the likelihood of discharge declines markedly after 2 years of hospitalization.

Aside from immeasurable operative variabilities, analysis of the factors which may have contributed to good or poor results in the lobotomy group revealed the following data. Correlation with the type of dementia praecox, as previously suggested (1), was quite well crystallized. Thus, only 10% of hebephrenic and simple subgroups were

out of the hospital, as compared with 28% of catatonic and paranoid subgroups and 50% of mixed or undetermined types. It may be inferred that those patients who exhibited hebephrenic features predominantly and relatively early in the course of the disease, i.e., those afflicted with so-called "nuclear" or "ingrained" dementia praecox, experienced generally poor results, while those whose disease pattern was admixed with affective or other "impure" schizophrenic features had the best outcome. In similar vein, although not so readily subject to statistical analysis, was the observation that withdrawn, inert, emotionally constricted and deteriorated patients exhibited generally poor results as compared with those who were aggressive, disturbed or emotionally reactive.

With respect to chronological factors, it was noted that 31% of patients whose illness began after the age of 25 were out of the hospital, as compared with only 19% of those whose illness began before age 25. Thus, earlier onset of illness was associated with poorer results. Similarly, with respect to chronicity of illness, the total duration of illness prior to operation was less than 5 years in 51% of the patients out of the hospital as compared with 30% of those still hospitalized.

Thus it may be concluded that frontal lobotomy, like all other known modes of therapy in schizophrenia, achieves its optimal results in patients whose illness is associated with long recognized favorable prognostic criteria.

AN EVALUATION OF AESCIN (AN EXTRACT OF HORSE CHESTNUTS) IN THE TREATMENT OF THE PSYCHOSES OF THE SENIUM

KENNETH LIFSHITZ, M.D., AND NATHAN S. KLINE, M.D.¹

Historically, the horse chestnut has been used as a folk remedy since the Middle Ages. In 19th century writings it is ascribed as having beneficial effects on varicose veins, ulcers, hemorrhoids and other diseases involving "venous and lymphatic congestion."

An extract of the horse chestnut (*Aesculus Hippocastanum*) has been made available, under the trade name of "Reparil."² "Reparil" is characterized as the sodium salt of aescin, a saponin. Over 50,000 doses of this substance have been administered to patients suffering from various forms of edematous reactions, such as the edemas following acute brain trauma, various bone fractures, and venous thromboses. The available German literature states that in these conditions aescin has been of value. Experimental studies indicate that aescin effects the selective permeability and the dynamic equilibrium of blood vessel walls. This plus the clinical observation of its favorable effect on the altered states of consciousness following acute brain trauma, led us to conduct a screening evaluation for any possible beneficial effects of aescin on patients ill with psychoses of the senium.³

The population sample which we used consisted of 10 patients, chronically ill; 8 having been diagnosed as "psychosis with cerebral arteriosclerosis" and 2 as "senile psychosis." The patients ranged in age from 62 to 76, with a mean age of 70 years. These patients had previously been followed for periods ranging from 1-2½ years in other pharmacological evaluation programs and were known to have shown no appreciable response to oral or intramuscular medications. The 10 patients served as their own controls. One of the reasons for the relatively small patient population was the necessity

for administering the aescin intravenously, since it is inactivated when administered by other routes.

The patients were initially evaluated for level of mental functioning and physical status; baseline hemograms and urinalyses were done. Blood chemistry determinations included serum glutamic oxaloacetic transaminase, blood urea nitrogen, and direct and indirect serum bilirubin (bilirubins were done, since it is known that horse chestnut extracts are to some degree hemolytic). The mental functioning evaluation consisted of 5 parts: a psychiatric interview, a scored mental status test, a scored evaluation by ward personnel, the "Wechsler Memory Scale," and 6 of the "Wechsler Adult Intelligence Scale" subtests, *i.e.*, information, arithmetic, digit span, vocabulary, picture completion, and block design. Laboratory determinations were done weekly, and the other evaluations at the beginning and end of the study.

Two milligrams of aescin solution were given daily intravenously, except Saturday and Sunday, to a total of 34 injections for each patient.

The evaluation of the results of therapy showed one patient with a mild improvement in overall mental functioning and 2 patients who appeared more cheerful and cooperative following therapy. These changes may have resulted from the drug or from the increased attention necessitated by daily I.V. injections. At the beginning of the study 6 patients showed a mild to moderate pedal edema. There was a progressive decrease in the amount of pedal edema in 5 of these patients. The laboratory studies showed no evidence of toxicity.

There was an overall decrease in the amount of pyuria shown in the group. One possible explanation of this is that because of its antiedematous action, aescin reduces the size of the hypertrophic prostate so prevalent in this age group with a resultant favorable effect on partial urinary obstruc-

¹ Rockland State Hospital, Orangeburg, New York.

² Aescin supplied as "Reparil" by Dr. Madaus & Co., Köln am Rhein.

³ The authors wish to thank Jacob Arnold, R.N. for his assistance in conducting this study.

tion. The indications that aescin has a generalized antiedematous action suggests that it may be of more value in situations where edema of the brain plays a pathological role, *e.g.*, acute brain trauma, early cerebral vascular accidents and perhaps epilepsies.

In summary, the administration of 34, 2 mg. I.V. injections of aescin to 10 patients with psychoses of the senium produced no significant beneficial effect on their mental function. Evaluation in other conditions, including uropathy with pyuria, should be considered.

DRUG-INDUCED HEPATIC INJURY: MARPLAN HEPATITIS¹

JAMES A. KNIGHT, M.D.²

The following case is reported because the findings are highly suggestive of a toxic hepatitis related to one of the amine-oxidase inhibitors, isocarboxazid (Marplan).

A 23-year-old white woman suffering from a moderately severe endogenous depression was started on Marplan, 10 mg. t.i.d., on December 1, 1959, and this dosage level was continued with one interruption until March 23, 1960. The patient was seen at weekly intervals and on February 24, 1960, complained of a skin rash. Medication was discontinued for 1 week, during which a dermatologist diagnosed the skin rash as pityriasis rosea and prescribed Benadryl. The Marplan regimen was resumed on March 2, 1960. The clinical assumption was that the rash was not related to the Marplan therapy.

During the patient's regular visit on March 23, 1960, her jaundice was noted immediately. During the preceding several days she had noticed a progressively deepening yellowness of her skin and eyes. She had a loss of appetite, and any intake of food was followed by nausea. Also she lost her taste for cigarettes. Her urine had become dark and her stools light. Marplan was discontinued, and the patient was hospitalized. The total amount of Marplan she had received was 3.18 gms.

On admission the positive physical findings were markedly icteric skin and sclerae; tenderness over the abdomen, especially in the right upper quadrant; hepatomegaly (liver margin palpable 4 cm. below costal margin); and disseminated erythematous scaling eruptions over the trunk and extremities, previously diagnosed as pityriasis rosea and now beginning to heal.

At admission several laboratory values were

elevated: SGP Transaminase, 540 u/ml.; SGO Transaminase, 150 u/ml.; alkaline phosphatase, 35 units (K-A); cephalin flocculation, 2+; thymol turbidity, 5.6; bromosulfalein retention, 8%; bilirubin, 6.8—indirect, 2.9, direct, 3.9. The urine contained bile. The following laboratory tests were normal and remained so throughout the illness: urea nitrogen, blood sugar, serum proteins, cholesterol, prothrombin time; hematologic studies, including hemoglobin, WBC, differential, platelet count, reticulocyte count, bleeding and clotting time; and serology.

The patient remained in the hospital 34 days. There was a gradual clearing of her jaundice, and she was asymptomatic at the time of discharge. She remained free of fever while in hospital. The elevated laboratory results returned to normal levels by the end of 3 weeks.

One week after hospitalization a needle biopsy of the liver was performed. The surgical pathology findings are given as they were reported by Dr. James C. Brennan:

"Microscopic Description: The portal triads in all areas are heavily infiltrated by inflammatory cells amongst which mononuclear cells predominate but polymorphs and significant numbers of eosinophils are present in all areas as well. The inflammatory exudate in the portal triads tends to erode into the peripheral limiting plate of liver cells and distort this area. Some of the liver cells at the periphery of the lobules have disintegrated into small cell lakes associated with bile stasis here. In the lobules there is irregular arrangement of liver cells in some areas and little or no change in others. A dominant feature is the presence of focal and rather irregular necrosis of liver cells occasionally with the formation of large acidophilic bodies which are being excreted into Disse's space. There is considerable nuclear regenerative activity in the central zones and the mid zones of these lobules whilst in the central

¹ Bibliography available on request.

² Assistant Professor of Psychiatry, Baylor University College of Medicine, Houston, Texas.

zones as well there is some atrophy and some excessive staining of liver cells by bile pigment. The histology presented favors more a toxic hepatitis than a purely allergic hepatitis or a viral infectious hepatitis.

"Diagnosis : Needle biopsy of Liver : Active toxic hepatitis (subacute), probably due to Marplan therapy. The presence of eosinophilia in the portal triads, usually associated with chlorpromazine-type hypersensitivity hepatitis, along with a subacute necrotizing process of the hepatic cells is a morphologic picture more commonly seen

with toxic drugs than with a primary necrotizing agent such as viral hepatitis where eosinophilia in the portal triads is relatively unusual. The absence of feathery degeneration or cell ballooning in the lobules is also against the diagnosis of infectious hepatitis."

Nine months have elapsed since the patient's discharge from the hospital, and she has remained free of any symptoms or signs of liver disease during that period.

Marplan has thus joined the ranks of Marsilid and Catron in producing hepatic toxicity.

EXPERIENCES WITH ELAVIL : TREATMENT OF FIFTY-ONE CASES OF DEPRESSION ¹

MAURIE D. PRESSMAN, M.D.,² AND LAWRENCE B. WEISS, M.D.³

Fifty-one cases of depression of various types (41, involuntional or reactive depressions) were treated with the new drug, Elavil. Most patients (45) were over 45 years old. Roughly, half were severely depressed and half mildly so. There was a special group of 20 depressed patients who also had hopeless physical situations. We consider this group of special interest.

Our patients were routinely placed on 100 mg. per day and dosage adjusted up or down, from 50 mg. to 200 mg. per day.

Results : Improvement usually began after 2½-3 weeks, but varied between extremes of 4 days to 6 weeks. Seventy-nine percent were moderately improved, greatly improved, or recovered. If these studies were corrected to exclude patients who had uncertain diagnoses, as well as those who did not faithfully take medication, these results would be even better.

The results in the patients who had depressions accompanying hopeless physical conditions (such as hemiplegia with aphasia, or advanced Kummelstiehl-Wilson's

disease) were gratifying ; 80% recovered or showed moderate to considerable improvement. One would have thought that these patients were depressed only in proportion to their physical disasters.

Medical observations : These were carried out in detail, as well as thorough laboratory testing (alkaline phosphatase, blood sugar, B.U.N., C.B.C., urinalysis, and, where indicated, other liver studies) and showed no hepatic or hematopoietic derangement.

Side Effects : Generally speaking, the side effects are unimportant, with the exception of marked torpor and sleepiness. This occurred in 18% and could be controlled by halving dosage for 5 days. Other side effects were : dizziness, sweats, hypotension, constipation, difficulty starting urine, blurred-dim vision, and epigastric burning. We believe that the side effects are less severe than with Tofrānil, Elavil's near relative, and that this drug has a beneficial tranquilizing effect which is absent with Tofrānil.

We would like to re-state our particular interest in the findings that the group of 20 patients, whose depressions accompanied very severe physical incapacity (such as C.V.A. with hemiplegia and aphasia), responded very well. The improvement in depression helped them to undertake physical therapy and rehabilitation which they had been unable to do before administration of anti-depressant medication. This allowed

¹ This study was made possible by a grant from Merck, Sharpe & Dohme. It was carried on at the Psychopharmacological Clinic of the Albert Einstein Medical Center, Northern Division, Philadelphia 47, Pa.

² Adjunct in Psychiatry, Albert Einstein Medical Center.

³ Chief, Psychopharmacological Clinic, Albert Einstein Medical Center. •

them to better their physical situations. We feel that the administration of anti-depressants to patients whose depression is *seemingly* in proportion only to their great physical loss, is a new area of application. It is our belief that very frequently such patients have a degree of depression and hopelessness which goes beyond a simple reaction to their physical impairment.

SERUM TRANSAMINASE TESTS FOR LIVER FUNCTION ON OUTPATIENTS IN FOLLOW-UP CLINIC

YUDELL K. SLOCUM, M.D.¹

A study was conducted on 90 outpatients who were receiving assorted ataractic drugs over a prolonged period. The purpose of this study was to determine whether or not continued treatment with the ataractic drugs would produce liver change. These patients had all been hospitalized prior to their outpatient care and had been treated with different ataraxics until their maintenance dosage on particular drugs was determined.

These patients had been mentally ill for a time range of 1 to 46 years. Forty patients (44%) had been ill from 1 to 10 years; 42 (47%) from 11 to 20 years; the remaining 8 (9%) over 20 years.

The age range of the patients was 25 to 67 years, average 42 years.

The time during which these patients received ataractic drugs on the follow-up service extended from 1 month to 4 years. Twenty-seven (30%) received medication for 1 to 6 months; 34 (38%) 7 to 12 months; 23 (26%) 2 to 4 years; the remaining 6 (6%) 2 to 4 years. The drugs prescribed were the 7 more commonly accepted ataraxics used today (Table 1).

The serum transaminase determination

¹ Veterans Administration Hospital, Northport, N. Y.

TABLE 1

Ataractic Drugs and Average Daily Dose of 90 Patients in a Follow-Up Clinic

NO. OF PATIENTS	DRUGS	AVERAGE DAILY DOSE (mg.)
26	Thorazine	150
20	Trilafon	24
13	Stelazine	6
13	Compazine	30
5	Mellaril	150
5	Vesprin	150
5	Equanil	400
3	Serpasil	.75

was done since it is an indicator of acute cellular damage of the liver due to any cause and has been recommended for periodic screening of patients maintained on drugs potentially toxic to the liver (1-3).

The study shows that of 90 outpatients on various levels of drugs, 89 had a normal transaminase test. One patient showed an abnormally high level (the lowest pathological level), although he continued treatment with the mildest ataraxic. He was a known alcoholic and the results of this test may have been due to a liver showing changes of damage prior to use of the drug (Equanil, 200 mg. daily dosage).

These tests followed a 4-year period of

treatment with the drugs. Although results were normal, it is still felt that a regular test of the liver and an occasional blood count should be done for the benefit of those receiving such medication.

CONCLUSIONS

The dosage of ataraxics which these patients were receiving was considered to be their maintenance dosage and the smallest amount of treatment necessary, which may be the reason for the negative reports of liver damage. The effect of the medication on the individual patient, not the medicine or chemicals themselves, must be the primary consideration in all treatments(4). It is felt that the medication has kept these

patients out of hospitals and helped them in adjusting for prolonged periods without the risk of harmful effects on the liver, even though they are not cured of their original mental illnesses(5).

IMIPRAMINE (TOFRANIL) IN THE TREATMENT OF ENURESIS

ANNA J. MUNSTER, M.D., ALFRED M. STANLEY, M.D., AND
JOHN C. SAUNDERS, M.D.¹

In a previous clinical note, MacLean² reported on the favorable results of giving imipramine to children for bed wetting. We initiated this study to evaluate further the efficacy of this method of treatment.

We selected 16 female patients from the same building with the chief complaint of "weakness," i.e., enuresis. All of these girls (ages 8-16 years) had previously cooperated in the hospital program for the relief of their enuresis. This program included psychotherapy, both individual and group as well as tranquilizers, voluntary fluid control and tincture of belladonna. With this treatment there was at times transient improvement but consistent relapses occurred often accompanied by guilt feelings and self-accusations. Other adolescents reacted to relapses not as personal failures but by rejecting their family or by attempting to manipulate the physician. Only those who presented a consistent pattern with high frequency of enuresis were selected for imipramine therapy.

We administered imipramine once at bed-

time either in dosage of 25 or 50 mg. depending on age and physical development. Patients under 12 years or over 12 but retarded physically, were given 25 mg.; those over 12 years or under 12 but physically precocious were given 50 mg. imipramine. The tranquilizers, reserpine or phenothiazine, which they were receiving, alone or in combination, for their psychoses were continued during the periods of imipramine therapy.

The response to treatment with imipramine was completely satisfactory in that all patients experienced alleviation of their enuresis and this confirms the findings reported.² The response to therapy occurred following the first dose and continued through the period of therapy. When the therapy was discontinued the enuresis returned immediately. We repeated the therapeutic cycle with imipramine 3 times and the response was consistent alleviation of enuresis while receiving the drug.

This effect cannot be interpreted as a placebo response since the girls continued to receive the tranquilizer therapy both with and without imipramine. If they were placebo responders at least some of them would have responded to one of the tranquilizers

¹ Rockland State Hospital and Research Facility, Orangeburg, N. Y.

² MacLean, R. E. G. : *Am. J. Psychiat.*, **117** : 511, 1960.

and that they did not do. The tranquilizer therapy was discontinued in one patient and she responded to the imipramine and enuresis returned when it was discontinued. Since MacLean used only imipramine we also conclude that it is the essential agent in controlling the enuresis.

In conclusion, we find imipramine to be

an effective and safe drug for the alleviation of enuresis in adolescent females and that this effect is not a placebo response is indicated by our study. The alleviation of enuresis permits home care or agency placement when previously this condition was put forward as an excuse to prevent acceptance.

DIABETIC CONTROL WITH CHLORPROPAMIDE IN A PSYCHIATRIC HOSPITAL : A PRELIMINARY REPORT

THOMAS G. LUPO, M.D., AND STANLEY M. TARNOWSKI, M.S.¹

Management of diabetes within a psychiatric hospital creates many special problems. We were interested in the practicability of converting a group of diabetic psychiatric patients from insulin to chlorpropamide (Diabinese).² Thirty diabetic patients whose psychiatric diagnoses were predominately schizophrenia were chosen for study. Insulin requirement for the group was 5 to 100 units; the age range 30 to 60 years.

During the control period and concurrent with the chlorpropamide medication, standard laboratory procedures relative to liver and renal functions, hematological aspects and glucose levels of body fluids were accomplished. Chlorpropamide substitution for insulin was on the basis of 100 mg. chlorpropamide for every 10 units of insulin administered. Those taking 20 or less units of insulin were immediately converted to the chlorpropamide. Those requiring from 20 to 100 units took up to 10 days for complete switch-over. Twenty-two patients were successfully converted from insulin to chlorpropamide. Nine patients whose insulin requirements were 5 to 25 units (usually NPH insulin) were satisfactorily controlled over a 6-month period with chlorpropamide. The initial dose was 250 mg. One patient of this group required 500 mg. of the drug daily for control. Another group of 9 patients required from 30 to 50 units of insulin daily. Their initial dose of chlorpropamide was 250 mg. Satisfactory diabetic control was accomplished over a 6-month period with dosages varying between 250 mg. to 500 mg.

daily. Four patients whose insulin requirements were 55 to 100 units daily were satisfactorily controlled for 6 months with 500 to 1000 mg. of chlorpropamide daily.

Eight patients originally included in the study were soon dropped because of the development of skin disorders resembling dermatitis medicamentosa (5 patients) and unsatisfactory diabetic control (3 patients). No permanent unfavorable side reactions relative to hematological, kidney or liver involvement were noted in this study.

Preliminary results indicate that in some patients with concurrent psychiatric conditions control of diabetes with chlorpropamide is practical. Twenty-two patients with insulin requirements up to 100 units daily were successfully converted to this oral hypoglycemic agent. Any reduction in the amount of work necessary to prepare and treat some 35 to 40 diabetics on a psychiatric ward is of course noticeable and very welcome. Our pilot study reduced the amount of necessary injections approximately one-half. One of the most satisfying results was a definite improvement in the morale and emotional outlook of diabetic patients. Most of them have come to accept the nurses, nursing assistants and ward physician as less punitive and dictatorial individuals. They are now more receptive of other avenues of approach and treatment of their psychiatric problems. The largest benefits will have been realized when these patients after returning to their homes, can enjoy a more carefree and normal existence. We readily recognize that the supervision of psychiatrically disabled individuals in their home environment is diffi-

¹ Veterans Administration Hospital, Waco, Tex.

² Supplied by Pfizer Laboratories.

cult enough without superimposing the problem of diabetes and the responsibilities which go with it. When the treatment of diabetes is reduced to that of merely taking a pill it so simplifies the patient's care and needs, that it allows the family to pay more attention to the emotional needs of the individual. Several patients have already gone on leaves of absence and trial visits, remaining away from the hospital as long as 3 months and have written to us reporting

that they are now realizing the benefits of oral hypoglycemic substitutes for insulin. Before they were released from the hospital, our primary concern was whether or not these patients and their families would accept the importance and seriousness of correct medication in the form of a pill with the same respect given previously to insulin. From the reports it appears that our fears were unwarranted. In the meantime our hospital study continues.

CASE REPORTS

EFFECT OF IMPRAMINE (TOFRANIL) ON DEPRESSION AND HYPERKINESIA IN HUNTINGTON'S DISEASE

J. WHITTIER, M.D., G. HAYDU, M.D., AND J. CRAWFORD, M.A.¹

Since Huntington's report in 1872(1), depression has been recognized as a frequent symptom in the syndrome of chronic progressive hereditary chorea.

A remarkable decrease in depression was observed under treatment with imipramine (Tofranil, Geigy) in a female outpatient having the disease.

A 41-year-old white housewife was referred for study to Creedmoor Institute in August 1959 by a local psychiatrist. Her mother had died at 71, having had Huntington's disease for 29 years.

Six years prior there had been onset of diminution in interest, slowing of activity, and fatigue. She was at that time found to be mildly hypertensive. Hyperkinesia appeared 4 years later, manifested by mild choreoid activity of feet or legs, extension-flexion movements of the trunk and inability to sit still, the latter especially noticeable during attendance at church. Gradually, depression appeared. Activities became effortful. She was bored with work, could not force herself to do housework or former hobbies, and began to lie down several hours each afternoon. With progression of the illness, she said that she wished she were dead, hated to return to the house after trips, stopped laughing altogether and smiled only rarely. It was soon necessary for her husband to bathe her, to help her dress, and to comb her hair. She began to remain bedfast most of the day due to weakness, became occasionally incontinent of urine and feces, retained food and saliva in her mouth for long periods, and had to be reminded to keep herself clean. There was gradual weight loss from 132 lbs. to 116. Medications had included reserpine to total daily dose 6 to 8 mg., which diminished the hyperkinesia somewhat, but was accompanied by somnolence.

Following examination at the Institute, recommendation was made to the local physician for a trial of imipramine 25 mg. t.i.d., increased to q.i.d. if no change ensued. One month later,

the husband reported that dosage had been increased to 100 mg. daily after 10 days, her mood had improved markedly, her appetite had increased, and she had begun to take interest in former activities. An increase in blood pressure was noted by her physician, and treated. Mood and behavioral improvements continued through the fall with family and friends recognizing "amazing change" from the previous summer. She returned to baking cakes and pies, no longer required assistance in bathing, dressing, or toilet care and took only occasional naps. Weight gradually increased to 139 lbs.

Re-examination at the Institute May 26, 1960, 9 months after imipramine was begun confirmed reports of change by physicians and family. Frequency, amplitude, and forcefulness of choreoid activity were noted to be somewhat increased.

The only other report of increase in the hyperkinesia of Huntington's disease under treatment with antidepressant medication known to us appeared in an entry under "side effects" in 1 case given tranylcypromine (Parnate, SKF)(2). Trial of imipramine and other antidepressants in treatment of depression associated with Huntington's disease, and systematic investigation of effect of these drugs on hyperkinesia appear warranted.

SUMMARY

A case of Huntington's disease is reported showing remarkable improvement in mood and behavioral manifestation of depression under treatment with imipramine. The choreoid hyperkinesia was observed to increase in severity.

REPORT OF A CASE OF CARCINOMA OF THE LUNG WITH METASTASIS TO THE BRAIN, SIMULATING PICK'S DISEASE

JAMES K. HALL, M.D.¹

The patient, a 64-year-old woman, was admitted to the sanatorium on October 9, 1955. She had had considerable examinations in other hospitals and by other physicians prior to admission to Westbrook. The patient had no complaints but she had shown personality change and failing memory since early 1954, at least. Neurological examination in December, 1954 was entirely normal, but x-ray of the left lung showed an "oval density 4 x 3 cms. near the periphery of the left first interspace. It was well-defined and apparently of long standing with no excavation." The impression was that degenerative cerebral disease was the most likely cause of symptoms. The nature of the pulmonary disease was undetermined at the time (December, 1954) and surgical intervention was decided against.

At examination in March 1955, the patient's indifference, perseveration, and memory difficulty had increased. Pneumoencephalogram revealed moderately diffuse cerebral atrophy with some dilatation of the ventricular system. Electroencephalogram was compatible with the diagnosis of cortical atrophy with evidence of greater involvement on the left side. No localizing neurological signs were found. Ophthalmologic examination revealed no significant ocular pathology and visual fields were full.

The patient remained at home between March and October, 1955 but her activities had to be restricted and this resulted in some irritability. She no longer could be allowed to drive a car after she side-swiped three or four cars one day. She claimed that happened when a package fell off the front seat and she reached down to get it. She and her husband went to Europe in the summer of 1955 and he noted that her reactions then were far from normal.

On admission to Westbrook, custodial care was all that was expected could be provided for the patient. The diagnosis of a presenile organic brain condition such as Pick's or Alzheimer's disease seemed assured. The lesion in the apex of the left lung was known to be present, but several x-rays had revealed no change in it. A psychological test on October 30, 1955 supported the diagnosis of chronic brain syndrome.

The patient died May 2, 1958. For several weeks she had gradually become weaker, there was some vomiting (probably of cerebral origin) and there was moderate fever. The downhill course continued despite treatment with antibiotics and intravenous feedings.

The patient's mental condition gradually deteriorated during hospitalization. She was at all times quite indifferent to her surroundings but usually pleasant and friendly in manner, although frequently restless and wandering about the building at night. Visits from family and friends seemed to mean little to her. She became progressively more untidy in her habits.

Autopsy revealed carcinoma of left upper lobe of lung with metastasis to lungs, anterior and posterior mediastinal lymph nodes, adrenals, thyroid, and cerebellum. There was compression of the fourth ventricle by metastatic tumor, and internal hydrocephalus. The cortex showed no appreciable loss of neurons, and no evidence of vascular disease. The brain stem showed no change other than pressure effect in the region of the fourth ventricle. Sections of the cerebellum showed adenocarcinoma identical to that seen in the lung and elsewhere, with abundant mucin production.

The lungs revealed the tracheo-bronchial tree filled with purulent mucus. Both lungs were studded with 1-2 mm. firm gray nodules throughout all lobes. In the left upper lobe there was a 6 cm. gray mucinous mass surrounding the superior segment bronchus. There was extensive involvement of lymph nodes in the chest cavity and of the adrenal medulla by metastatic carcinoma.

The liver, pituitary, heart, aorta, skin, pancreas, and spleen were not remarkable.

The brain in the fixed state weighed 1450 grams. The dura was adherent to the skull, the vessels showed no appreciable atheromatous deposit. The left meninges were somewhat cloudy. There was no appreciable widening of the sulci nor narrowing of the gyri. The vessels at the base of the brain were delicate and showed very minimal atherosclerosis. No thrombi were demonstrated. Multiple parallel sections were made through the brain. The lateral ventricles were considerably dilated, as was the third. No focal lesions were seen in the cerebral hemispheres. The aqueduct of Sylvius was dilated. The central portion of the

¹ Westbrook Sanatorium, Richmond 27, Va.

cerebellum was replaced by a 5 cm. mucinous tumor lying in the midline, adherent to the dura, and compressing the fourth ventricle which was not dilated distal to the point of compression.

It would seem probable that this patient's brain pathology and mental symptoms were due entirely to the metastatic tumor in the cerebellum which resulted in internal hydrocephalus. The patient had given evidence of organic brain disease for at least 4 years.

The case is considered interesting because there were no localizing neurologic signs despite extensive involvement of the cerebellum, and the patient's mental condition seemed so typical of a presenile organic disease such as Pick's. The increased incidence of lung cancer may be expected to result in other cases with intracranial metastasis and organic brain symptomatology.

COMMENTS

CHICAGO MEETING HIGHLIGHTS

The 117th Annual Meeting of the American Psychiatric Association was held at the Morrison Hotel, Chicago, Illinois, May 8-12, 1961. The total registration was 4,292 including 2,054 members, 1,385 non-members, 519 wives of members, 274 exhibitors and 60 press representatives. The Program included 123 scientific papers and 24 Round Tables.

The opening exercises were called to order by the President, Dr. Robert H. Felix, at 9:30 a.m. on May 8. The Invocation was given by the Right Reverend Gerald Francis Burrill, Episcopal Bishop of Chicago, followed by welcoming remarks by the Honorable Otto Kerner, Governor of Illinois. After the President had introduced Dr. Walter E. Barton, President-Elect, several Awards were presented. Professor Sheldon Glueck, Roscoe Pound Professor of Law at Harvard, was announced as the 10th winner of Isaac Ray Award for outstanding contributions in furthering understanding between the law and psychiatry. As recipient he will deliver a series of lectures at Tulane University during the 1961-1962 academic year. The Hofheimer Prize was awarded to Seymour Levine, Ph.D., of the Maudsley Hospital in England and several co-researchers for studies on infantile experience and the effects thereof upon maturation of the neuroendocrine system. The winner of the 1960 Mental Hospital Achievement Award was the Larned (Kansas) State Hospital, with Honorable Mention Awards to the Mental Health Institute of Clarinda, Iowa and to the New Jersey State Hospital at Marlboro. Reports were presented by Dr. John R. Saunders, Speaker of the Assembly; Dr. Mathew Ross, Medical Director; Dr. C. Knight Aldrich, Co-Chairman of the Arrangements Committee; and Dr. John Donnelly, Chairman of the Program Committee. The Secretary, Dr. C. H. Hardin Branch, announced the official membership count as of March 31, 1961 as 11,637 and the Treasurer, Dr. Addison M. Duval, presented a financial report. The

membership was considerably enlarged with the approval of the candidates recommended by the Membership Committee and the Council. A total of 682 new members were added—372 Associate Members and 310 Members. Of this number, 10 Associate Members and 7 Members had previously been approved by certified District Branches so that further action was not necessary. An additional 180 candidates were advanced from Member to Fellow. Upon recommendation by the Policy Committee and the Council, the Prairie Provinces District Branch (Alberta, Manitoba and Saskatchewan) was approved by the membership bringing the number in the Assembly to 53. The Presidential Address, entitled "Psychiatrist, Medicinæ Doctor," was delivered by Dr. Felix with the response by Dr. Barton. Dr. Earl Bond read a Memorial to the late Past-President Arthur H. Ruggles which was followed by a moment of silence in memory of the deceased members of the Association. The Opening Exercises were closed with a Benediction by the Reverend Vincent V. Herr, S.J., Chairman of the Psychology Department of Loyola University, Chicago.

The first Business Session was called to order by the President on Tuesday afternoon, May 9, at 2:00. Dr. Evelyn Ivey, Chairman of the Board of Tellers, announced the results of the election of Officers for 1960-61 as follows: Dr. C. H. Hardin Branch, President-Elect; Dr. Henry W. Brosin, Vice-President; Dr. Titus H. Harris, Vice-President; Dr. Harvey J. Tompkins, Secretary; Dr. Addison M. Duval, Treasurer; and incoming Councilors, Dr. Alfred Auerback, Dr. Herbert S. Ripley, and Dr. Cecil L. Wittson. Reports were presented by the three Coordinating Committee Chairmen: Dr. Harvey J. Tompkins, Technical Aspects of Psychiatry; Dr. Howard P. Rome, Professional Standards; and Dr. Paul V. Lemkau, Community Aspects of Psychiatry. After a brief recess, the Convocation of Newly Elected

Fellows began with the Processional March at 3:00 p.m. A total of 133 new Fellows attended the ceremony. The Fellowship Lecture was presented by Dr. Seymour S. Kety, Chief, Laboratory of Clinical Science, National Institute of Mental Health, on "The Heuristic Aspect of Psychiatry." The ceremony was concluded with a Recessional March.

The second Business Session was held on Wednesday morning, May 10, and was called to order by the President at 9:30 a.m. The Secretary presented his report to the membership reviewing the actions of the Council since the last Annual Meeting. These were approved on motion from the floor. The most significant item in the report was a proposed raise of dues in the amount of \$5.00 for Associate Members and \$10.00 for Members and Fellows. This proposal was approved by the Council as recommended by the Budget Committee. Following a discussion of the matter, the proposal was approved as a separate item of business.

The Annual Dinner was held on Wednesday evening at 7:30 in the Terrace Casino of the Morrison Hotel. The President introduced the foreign guests and the representatives of other professional associations who were in attendance. Dr. D. Ewen Cameron presented inscribed gavels to each of the eight Past-Speakers of the Assembly: Dr. Joseph Abramson, 1953-1954; the late C. N. Baganz, 1954-1955, received posthumously by Mrs. Baganz; Dr. Addison M. Duval, 1955-1956; Dr. Mathew Ross, 1956-1957; Dr. Walter H. Obenauf, 1957-1958; Dr. David C. Wilson, 1958-1959, received in absentia; Dr. Alfred Auerback, 1959-1960; and Dr. John R. Saunders, 1960-1961. The Past-President's Pin was presented to Dr. Felix by Dr. Earl D. Bond, the oldest surviving Past-President. The evening's entertainment was concluded with dancing.

The final Business Session was held on Friday morning, May 12, at 11:30. After calling the meeting to order, Dr. Felix spoke briefly regarding his Presidency and expressed his appreciation to the membership and to the staff for their assistance and cooperation during his term of office. He then installed Dr. Barton as President. Following Dr. Barton's remarks, Dr. Felix read

the names of the Committee Chairmen and Councillors who were retiring from office. The Secretary reported the actions of the Council from its meeting on May 11 and these were approved by the membership upon motion from the floor.

The Adolf Meyer Lecture was presented by Dr. John Bowlby, Corresponding Fellow, of London, England on "Childhood Mourning and Its Implications for Psychiatry." Two papers on communication presented by invitation were well-received: "Communication Amongst Automata" by Heinz Von Foerster, Ph.D., Professor of Electrical Engineering at the University of Illinois, and "Animal Communication" by Hubert W. Frings, Ph.D., Professor of Zoology at Pennsylvania State University.

The Assembly met on May 8-9 with representatives of 51 of 53 District Branches in attendance. Their Officers for 1961-1962 are Dr. Edward Billings, Speaker; Dr. G. Wilse Robinson, Jr., Speaker-Elect; Dr. Lester Shapiro, Recorder; and Dr. John R. Saunders, Past-Speaker. Area Members of the Policy Committee are Northeast (I), Dr. Robert Garber, Member, and Dr. Benjamin Wiesel, Alternate; New York (II), Dr. William Holt, Member, and Dr. Duncan Whitehead, Alternate; Southern (III), Dr. Hamilton Ford, Member, and Dr. Frederick Woodson, Alternate; Midwest (IV), Dr. Philip Reed, Member, and Dr. Ewing Crawfis, Alternate; Western (V), Dr. G. Creswell Burnes, Member, and Dr. Barnard L. Diamond, Alternate. Dr. Walter H. Obenauf will again serve as Parliamentarian for the Assembly.

The annual luncheon of the Modern Founders was held on Wednesday, May 10, in the Clark Room of the Morrison Hotel with Dr. and Mrs. Francis J. Gerty acting as hosts. Approximately 60 members and guests were in attendance including 5 new Modern Founders who were welcomed into the group.

In addition to the events mentioned above, there were numerous meetings, luncheons, reunions and parties all of which helped make this Annual Meeting such an eminent success. It was altogether fitting for a scientific and social meeting of this significance to climax the activities of the Association during the past year under the

guidance of our immediate Past-President, Dr. Robert Felix. And as Dr. Felix noted at the final Business Session, special recognition should be given to the Officers, the Committee members and the staff for their invaluable service throughout the year. However, on this occasion it seems appropriate to commend the work of the several Committees and staff members

whose collaborative efforts were instrumental in the success of this Annual Meeting : Mr. Austin M. Davies, the Executive Assistant ; Dr. Mathew Ross, Medical Director ; Messrs. Robinson and Turgeon of the Central Office ; and particularly the Committees on Arrangements and Program.

C. H. Hardin Branch, M.D.,
Secretary.

WHEN IS A DOCTOR NOT A DOCTOR ?

From the A.M.A. news of the recent past we quote with permission the story of an East German physician who had taken refuge in West Germany. When questioned as to his feelings about deserting his patients in East Germany he said :

"The question comes to my mind : Was I still a doctor before I decided to leave ? Is anyone still a doctor who cannot really heal people because he lacks the right facilities and is supposed to feed his patients political slogans instead of medicines ? Is a doctor still a doctor if the state and party reduce him to a mere state functionary ; if he is

asked to work as a party propagandist ; if he is ordered to declare sick people fit to work against his better knowledge, if he is given insufficient means to heal and to help and if he is hemmed in on all sides ?

"Can he sleep with a clear conscience, can he still call himself a doctor if, against his conscience, he is compelled to carry out orders given him by the government, even though he knows these orders are not in the best interests of the sick, but only in the interests of the state and the party ?"

And this refugee doctor concluded "that I really was not a doctor any longer."

THE EDITORIAL BOARD

Owing to the resignation of Dr. John C. Whitehorn, professor emeritus of psychiatry, Johns Hopkins University School of Medicine, a new name appears among the associate editors this month. Dr. Whitehorn had given a long period of valuable service to the Editorial Board, aiding by his counsel in the shaping of policy, and making important and often quoted contributions to the pages of the *Journal* ; we shall feel assured in seeking his counsel in the future as in the past as occasion may arise.

At the meeting of the Editorial Board, May 9, it was unanimously voted to present to Council the name of Dr. Lorne D. Proctor, head of the department of neurology and psychiatry, the Henry Ford Hospital, Detroit, to fill the vacancy. At the meeting of Council, May 11, this was done and by vote without debate the appointment was

duly recorded. Dr. Proctor is a diplomate of the Royal College of Physicians of Canada as well as of the American Board of Psychiatry and Neurology. He is a member of the American Academy of Neurology and of the venerable College of Physicians of Philadelphia. For some years he collaborated with Sir Frederick Banting as research associate, and during his 10 years service with the Henry Ford Hospital one of his most significant achievements was the organizing in 1957 of the International Symposium on the Reticular Formation. He collected and edited the proceedings of the Symposium which were published in book form in 1958.

We feel that Dr. Proctor's membership will notably strengthen the Editorial Board and we welcome him to this fellowship.

CORRESPONDENCE

TREATMENT OF CARDIAC ARREST

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR: The article, "Cardiac Arrest and Electroshock Therapy," by Genevieve A. Arneson, M.D., and Tarver Butler, M.D., which appeared in the May 1961 issue of *The American Journal of Psychiatry*, was of great interest to me.

Last year I had a patient who developed cardiac arrest. The arrest, however, developed following the administration of intravenous Evipal with Succinyl. The patient was administered 300 mg. of Evipal, intravenously, over a one-minute period. This was followed by 60 mg. Succinyl, intravenously. As is usual with this procedure, positive pressure oxygen was immediately instituted. Despite the oxygenation, the patient developed cyanosis. His pulse could not be elicited nor could heart sounds be detected by stethoscope. A diagnosis of cardiac arrest was made by two physicians who were present. From our Reiter, Model CW-47, electric shock apparatus, one electrode was placed posterior to the heart and the other electrode over the precordium. $\frac{1}{2}$ second shock of 50 milliamperage, 110-volt current, was administered three times

over a period of five to ten seconds. Almost immediately the cyanosis began to clear. The pulse was now discernible and soon became full and strong. The heart sounds returned. No shock treatment, in the ordinary sense, was administered. Within five minutes the patient was awake and talking. His blood pressure was now within normal limits. Electrocardiogram revealed no abnormalities.

It is believed that the cardiac arrest occurred because of sensitivity to the Evipal. I believe that the use of the ordinary electric shock apparatus in restoring his heartbeat was life-saving. Psychiatrists who encounter the complication of cardiac arrest in the future might find it worthwhile to consider that they have at hand a very potent instrument for stimulating the heart. Further thought might be given to this method of cardiac resuscitation.

I believe this procedure might be useful in restoring the heartbeat where the arrest has occurred from electric shock treatment, surgery or other causes.

Corbett H. Thigpen, M.D.,
Augusta, Ga.

PHILOSOPHY TOMORROW

Philosophy still has a work to do. It may gain a role for itself by turning to consideration of why it is that man is now so alienated from man. It may turn to the projection of large generous hypotheses which, if used as plans of action, will give intellectual direction to men in search of ways to make the world more one of worth and significance, more homelike, in fact. There is no phase of life, educational, economic, political, religious, in which inquiry may not aid in bringing to birth that world which Matthew Arnold rightly said was as yet unborn. Present-day philosophy cannot desire a better work than to engage in the act of midwifery that was assigned to it by Socrates twenty-five hundred years ago.

—JOHN DEWEY

NEWS AND NOTES

DEPARTMENT OF PSYCHIATRY AT THE UNIVERSITY OF VERMONT COLLEGE OF MEDICINE.—The office of the Dean has announced the establishment of a department of psychiatry. Previously, psychiatry has been a division of the department of medicine. Chairman of the newly created department is Dr. Thomas J. Boag, assistant to the Director of the Allan Memorial Institute of Psychiatry and an Assistant Professor at McGill University. Dr. Boag, a native of Liverpool, England, received his medical degree from the University of Liverpool.

He will take up his new duties at the University of Vermont College of Medicine on July 1 as a full-time Professor and Chairman of the Department of Psychiatry.

NATIONAL COUNCIL ON CRIME AND DELINQUENCY.—The national Research and Information Center on Crime and Delinquency of the National Council has been established as a clearing house for current research and projects to control crime and to prevent juvenile delinquency. The Center is supported by grants from the Rockefeller Brothers Fund and the National Institute for Mental Health of the Department of Health, Education, and Welfare. It is located at 44 E. 23rd St., New York 10, N. Y.

It will collect and disseminate information not only on research, but also on all programs in institutions and services, experiments, developments and demonstrations. Dr. Hyman H. Frankel is Director of the Center.

THE PHILADELPHIA PSYCHIATRIC HOSPITAL.—The appointment of Dr. Philip Mechanick as Medical Director of the Philadelphia Psychiatric Hospital has been announced by Mr. Abe Cooper, President of the Hospital.

Dr. Mechanick, a diplomate in psychiatry has been associated with the Hospital since 1955. He has served as Clinical Director and Acting Medical Director. He is a graduate of the University of California Medical

School in San Francisco and received his psychiatric residency training at Langley Porter Clinic, San Francisco.

LOS ANGELES SOCIETY OF NEUROLOGY AND PSYCHIATRY.—At the annual meeting of the Society, January 18, 1961, the following officers were elected: President, Nicholas A. Bercel, M.D.; President-Elect, Robert P. Sedgwick, M.D.; Secretary-Treasurer, Robert N. Baker, M.D.

Councilors: John D. French, M.D., Augustus S. Rose, M.D., G. Creswell Burns, M.D., Carlo P. DeAntonio, M.D., John R. Peters, M.D.

FOUNDATIONS' FUND FOR RESEARCH IN PSYCHIATRY.—The Foundations' Fund announces the award of four grants of \$250,000 each toward the endowment of four permanent research positions in departments of psychiatry. Awards have been made to the psychiatry departments of the following universities: University of Chicago School of Medicine, Columbia University College of Physicians and Surgeons, University of Utah College of Medicine, and Yale University School of Medicine. Each of these medical schools will appoint a research psychiatrist to the newly created position on their faculty.

These awards were made possible by a 1956 grant from the Ford Foundation to the Foundations' Fund for Research in Psychiatry for the support of the training of psychiatric investigators in the mental health fields.

Max M. Levin, Ph.D., 251 Edwards St., New Haven 11, Conn. is executive officer of the Fund, and F. C. Redlich, M.D., professor of psychiatry, Yale University School of Medicine is chairman of the Board of Directors.

MCLEAN HOSPITAL'S 150TH ANNIVERSARY.—On May 15 and 16, 1961 a two-day symposium, "A Multidisciplinary Research Program in a Mental Hospital," was held at historic McLean Hospital to commemorate

the 150th anniversary of the incorporation of McLean and Massachusetts General Hospitals.

On May 15 the new additions to the research laboratory were dedicated, and a neurobiological program was presented. Dr. Jordi Folch-Pi, professor of neurochemistry, Harvard Medical School and director of research, at McLean, was in charge.

The May 16 session, under the direction of Dr. Alfred H. Stanton, associate professor of psychiatry, Harvard Medical School and psychiatrist in chief, McLean Hospital, was devoted to behavioral and clinical studies.

Eminent speakers, beside those from McLean and Massachusetts General Hospitals and Harvard University staffs, came from the Universities of Colorado, Michigan, Johns Hopkins, Yale, New York and Columbia, the Rockefeller Institute, the Judge Baker Guidance Clinic, Mass. Institute of Technology and N. Y. State Psychiatric Institute.

AMERICAN BOARD OF PSYCHIATRY AND NEUROLOGY, INC.—The following physicians are reported as having been certified in the sub-specialty of Child Psychiatry in March, 1961:

Milford E. Barnes, Jr., M.D., Des Moines, Iowa.
H. Robert Blank, M.D., White Plains, N. Y.
Richard Leos Jenkins, A.B., M.D., Iowa City, Iowa.
Reynold A. Jensen, M.D., Minneapolis, Minn.
Paul Hartley Jordan, Flint, Mich.
C. Raymond Kiefer, Jr., M.D., Hartford, Conn.
Margaret Schoenberger Mahler, M.D., New York, N. Y.
Samuel Rosmarin, M.D., White Plains, N. Y.
Earle Saxe, M.D., New York, N. Y.
Louis A. Schwartz, M.D., Detroit, Mich.
Lenore M. Sportsman, M.D., Albany, N. Y.
Florence Lillian Swanson, M.D., Montclair, N. J.

AMERICAN ACADEMY OF ARTS AND SCIENCES.—In 1961, as in the preceding two

years, the Academy will offer three prizes of \$1,000 each to the authors of especially meritorious unpublished monographs, one each in the fields of: 1. Humanities; 2. Social Sciences; and 3. Physical and Biological Sciences. The final date in 1961 for receipt of manuscripts by the committee on awards is Oct. 2.

Full details concerning these prizes may be secured on request by sending a stamped self-addressed envelope to the Committee on Monograph Prizes, American Academy of Arts and Sciences, Little Hall 33, Harvard University, Cambridge 38, Mass.

RORSCHACH.—The fifth International Congress is to be held Aug. 5-9, 1961, in the University of Freiburg in Breisgau, Germany. Professor R. Heiss is President of the Congress.

The principal papers to be read are by S. J. Beck, Chicago, R. Kuhn, Münsterringen, Switzerland, and a third contributor, to be announced, from Italy.

In addition the following special areas are to be explored:

1. Theoretic and empiric foundations of Rorschach technic;
2. Application in the fields of medicine, development, and social psychology;
3. Rorschach technic in relation to other psychological procedures;
4. Modifications and new developments;
5. Problems of international agreement on signs and evaluations.

Headquarters of the Congress are at the Institut für Psychologie und Charakterologie, Peterstr.1.(Peterhof), Freiburg inn Breisgau, Germany.

TO BEGIN WITH

You learn to consume your own smoke. The atmosphere is darkened by the murmurings and whisperings of men and women over the non-essentials, the trifles that were inevitably incident to the hurly-burly of the day's routine.

—OSLER

BOOK REVIEWS

COMMANDANT OF AUSCHWITZ; THE AUTOBIOGRAPHY OF RUDOLF HOESS. Trans. by *Constantine FitzGibbon*. (Cleveland and New York: The World Publishing Co., 1959, pp. 279. \$4.50.)

The autobiography of Rudolf Hoess, who organized and personally observed the gassing of two million Jews in the German extermination camp in Auschwitz, is an invaluable document for everybody concerned with the mysteries of the human "mind." We are indebted to the Polish physician responsible for Hoess's care in the prison who encouraged him to put his memoirs on paper while he was awaiting his execution.

The reader may not find answers to all questions that may come to his mind, but the book may lead to a clearer formulation of questions about the interplay of motivations responsible for such a phenomenon as Rudolf Hoess.

Except for a short psychotic depressive episode while in jail after World War I, a "Gansers Syndrome," there is no evidence in Hoess's autobiography that he was suffering from an unusual degree of neurotic or psychotic "psychopathology." His family background and early development are typical for the German middle class of his era. Yet this man acquired a degree of detachment and dissociation from cultural values that the most "autistic" schizophrenics do not easily achieve. It does not seem to have occurred to Hoess that there was anything bad or even unusual in killing millions of people in gas ovens. The only "explanation" he offers is that the Jews were "bad" for the German nation, but he shows no evidence of any particular need for further explanation or rationalization why they were so bad. This indicates a considerable ability for the suppression of questions which anybody with a normal I.Q. could barely avoid asking; an ability which was shared to a greater or lesser extent by the majority of the Germans of the Hitlerian era.

The inside story of Auschwitz and other extermination camps was not kept as secret as Hoess's book claims. This reviewer lived in close vicinity to the Belzec extermination camp and was, as was everybody else living there, exposed for 2 years to the smell of the burning bodies of gassed victims. Also, she heard many descriptions of the happenings from escaped Polish prisoners from Auschwitz and other

camps which were practically identical with Hoess's descriptions.

The German occupational forces in Poland who were not members of the Gestapo deliberately avoided any too thorough knowledge of these unpleasant facts, but why the Western powers' allied broadcasts and press did not give them more space remains a mystery since they were well informed of these by the Polish underground. The German propaganda machine certainly put considerable efforts in informing the whole world of the Russian massacre in Katyn.

The dissociation from accepted cultural values revealed by Hoess and the whole German nation was, however, localized to only certain issues. One of them was: The Jews "had" to be exterminated. The process itself was designed as "humanely" and "atraumatically" as possible. Hoess considered himself a member of a humane culture emphasizing his preference for a bucolic life plowing fields, raising animals, and regretted that his killing job interfered with it. He expressed warmth and sympathy for the harmless gypsies, regretting as sincerely that he had to exterminate them as anybody would regret having to drown a litter of cute little kittens. He seems to have been a good husband and father. For this reviewer one of the most gruesome parts of the book is his describing how much he and his wife enjoyed rearing their children and growing beautiful flowers—right under the smell of burning bodies of the victims whose gassing he personally witnessed through a peephole once or twice a week.

Nowhere in the book does Hoess indicate any basic objection to the extermination of the Jews. His final conclusion was only that it was not very practical because the bad reputation it made for the Germans was possibly more unfavorable for them than the survival of the Jews would have been.

To the end of the book he considers himself not a villain, but rather a victim of adverse circumstances, and at least the second part of his conclusion, that *vae victis* is still the dogma No. 1 of international justice may well be shared by those who followed the trials in Nuremberg, where the executors of Katyn were judging the executors of Auschwitz.

A few interesting omissions in the book suggest, however, that Hoess must not have felt equally comfortable about all of the Fuehrer's extermination ideas. His description of the pre-

war concentration camps mentions only communists, socialists, religious conscientious objectors and asocials as prisoners. The considerable number of German aristocracy imprisoned was not mentioned at all. When this reviewer was also imprisoned and met this group of prisoners, she noticed the Gestapo seemed to have failed to share Hitler's idea that the members of the German aristocracy in the camp were a danger to the nation, despite their uncompromising anti-Nazi attitude. Hoess also fails to mention the large number of Catholic priests who perished in Auschwitz.

The book fails to shed any light on the "reasons" for the Nazi obsession of exterminating the Jews. It had no practical value whatsoever even to rationalize its cruelty. To "explain" it as an extension of "antisemitism" is an oversimplification because tensions between different cultural groups have always existed, but only seldom led to such radical "solutions." Maybe Eichmann can one day answer some of the questions not answered in Hoess's book.

This book is, however, an impressive illustration of the degree to which "reason" can be suppressed by perfectly sane people in our "age of reason," and if the reader is a psychiatrist, he could wonder whether the so-called psychopathologies could not be connected with a failure of suppressive mechanisms, which seem to play an important role in "normal" psychology.

HILDA MUSZYNSKI, M.D.,
Nevada, Mo.

IN DEFENSE OF MOTHERS. 4th Ed. By Leo Kanner, M.D. (Springfield, Ill.: Charles C Thomas, 1958, illus., pp. 167. \$3.50.)

Dr. Kanner wrote this book in 1941. His subtitle is "How to Bring Up Children in Spite of the More Zealous Psychologists." In its several editions it has not been necessary to revise the text. The book is as good today as when it was written 20 years ago, because its guiding theme is not some specialized, highly refined technique with its lists of *dos* and *don'ts*, but rather a regime of disciplined common sense on the parents' part, in the rearing of children.

No one is better qualified than Kanner, the creator of child psychiatry in the United States, to write such a book of instruction, so simple, so elementary and yet so profoundly wise. He writes with a light touch, often jocularly; tells true stories to illustrate parental problems and the obvious but untried way to deal with them. You say to yourself "why didn't I think of that?" Maybe you will next time. Beware, when your child has a tantrum, that you don't

have one too. And don't put too much emphasis on things *verboten*. Do not listen when one of "the more zealous" experts tells you, as one of them once did, that *Alice in Wonderland* is bad for children. The real Alice, who lacked the benefits of that professional knowledge, recalling many years later the effect of Mr. Dodgson's stories on herself and her little sisters, put it quite simply: "we were thoroughly happy and amused at his stories . . . we looked forward to the happy hours in the mathematical tutor's rooms."

From his case records Kanner gives vivid pictures of regrettable scenes of parental mismanagement which he assures us are not "caricatures drawn for literary effect . . . They are ordinary occurrences in thousands of ordinary dwellings . . . yes, even in the homes of psychologists and psychiatrists." These tableaux are presented in such a way that they carry their own indications for treatment. And so often children's complaining habits of all sorts are only a part of the general family picture. The unfortunate thing is that with so many persons, discussion of illness, indisposition, symptoms past or present is so large a part of their conversation at home and abroad. "There are children who are treated from the beginning as if they were their parent's hypochondriacal organs."

Kanner denounces the custom, taken over from doctors and continued by parents and the neighbors, of labeling a child who seems unusual in some undesired way—calling him neurotic or introvert or psychopathic or schizoid—"libeling" he calls it or "swearing at" the unfortunate child. He wants children dealt with as persons not as cases of this or that.

Then there is a chapter on thumb sucking, of which some experts give a sexual interpretation. Kanner is allergic to that view and concludes with the question which he says can't be asked too often, "so what?"

He reaches Hudibrastic heights in the next chapter that bears the caption, The Great God Unconscious, which he abbreviates through the text to G.G.U. He gives in some detail the Kanner version of the G.G.U. with all His (capital H) derivatives, associates and complexes. His final admonition—"If, after what you have read, you want to go on worshipping the Great God Unconscious and His cocksure interpreters, there is nothing to keep you from it. But do not let your children pay the penalty for your own excursions into the realm of fancy."

If Dr. Kanner's little book were available to mothers generally, especially to new mothers, the country could do with fewer child psy-

chiatrists. It should be prescribed reading for both pediatricians and child psychiatrists; and doctors generally would take no harm from consulting it. It is entertaining as well as instructive. Even fathers could profit by exchanging the sport pages now and then for a dip into the *Defense of Mothers*.

It well documents an old German proverb and moreover advises what can be done about the dilemma:

Vater } werden ist nicht schwer;
Mutter }

Vater } sein dagegen sehr.
Mutter }

C. B. F.

THOUGHT REFORM AND THE PSYCHOLOGY OF TOTALISM. By Robert Jay Lifton, M.D. (New York: W. W. Norton and Co. Inc., 1961, pp. 510. \$6.75.)

The sub-title of this book is "A Study of 'Brainwashing' in China." It is a book of horrors.

Dr. Lifton is a research associate in psychiatry and an associate of the Center for East Asian Studies at Harvard University. He served as an Air Force psychiatrist in Japan and Korea, 1952-53, and remained in the Far East to do the investigation described herein. He spent nearly two years in Hong Kong studying persons, both Western civilians and Chinese intellectuals, who had been put through the "Thought reform" machine in China.

The voluminous material accumulated has enabled the author to set forth in detail the psychological (and physical) atrocities committed by the Communist masters of China in purging the minds of their victims of whatever standards of life and thought and behavior they may have had and engrafting in their place the Credo of the Party. And more than the Credo is involved; the individual has to be made over, his sense of personal identity and integrity has to be destroyed and a new Kamerad-personality developed in its place.

The book describes the details of this process. Its climax is the "Confession," exemplified many times in the past, a subversion vastly more drastic than the ordinary religious conversion. If the word *human* means anything because from it the word *humane* is derived, then the psychological torture of this form of brainwashing is the ultimate of the inhuman and the horrible.

The Chinese Communists do not have to hurry, they can take their time and if necessary the "reform" process may consume as many months or years as a thorough psychoanalysis.

It seems at least questionable that from the continuous, concentrated, protracted, destructive pressure brought to bear on the isolated mind of the prisoner complete recovery is ever possible.

The author makes no pretense that he can remain unbiased in his study of this almost incredible psychological torture of the helpless individual; but he nevertheless sets forth as precisely as possible the data collected in his interviews with the victims of Chinese "Thought reform."

At the end of his book Lifton discusses the psychological problem of what he calls "ideological totalism," the potential of which in however small degree is a common human characteristic. Through a confluence of certain conditions which he recites any emotionally-charged ideology may lead in a "totalistic"—Messianic—direction. "And where totalism exists, a religion, a political movement or even a scientific organization becomes little more than an exclusive cult." This kind of totalism may be found in any society and is of course to be guarded against. Its aggressive promulgation is also a variety of brainwashing.

Lifton's book is a detailed textbook of Chinese Communist methods of tearing down the individual personality and engrafting the Party model, with wider reference also to the processes through which a totalitarian society can be molded and leveled to conformity.

C. B. F.

AUFTEILUNG DER ENDOGENEN PSYCHOSEN. (The Classification of Endogenous Psychoses). Second Edition. By Karl Leonhard. (Berlin: Akademie-Verlag, 1959, pp. 539.)

It is customary to consider the manic and "melancholic" diseases in the frame of manic-depressive psychoses. Kleist considers them as two conditions that have an affinity for each other. While the author agrees with Neele that there is a manic-depressive combination that expands in opposite directions, there are also euphoric and depressive states that are separate entities unrelated to each other. The combined diseases are designated as bipolar, the separate ones as monopolar.

The bipolar psychopathologies are more colorful and varied and they sway not only from pole to pole, but even within the limits of the same phase they have various symptom-pictures. However, the monopolar forms re-assume periodically the very same symptomatology, retaining in each phase its circum-

scribed and pure form without any admixture of symptoms of the other phase.

The classical symptomatology of the manic-depressive reactions, as they were first described by Kraepelin, is as follows. In the manic stage there is : a euphoria that passes easily into irritability, heightened self consciousness, flight of ideas, speech compulsiveness and hyperactivity. In the depressive state there is a weariness with life, feelings of inadequacy, thinking difficulty, psychomotor inhibitions, lack of decisiveness, depressive thinking and self-accusations. However, in the bipolar term the basic symptoms may be missing : hyperactivity, flight of ideas and even euphoria may be absent in the manic phase and difficulty of thinking and psychomotor inhibitions may not be present in the depressive phase.

The author also discusses in great detail and with ample clinical observations other forms of mental aberrations under names that are not familiar to American psychiatrists. Thus he presents 4 "cycloid" psychoses : anxiety-happiness, irritation-inhibition, hyperkinesis and akinesis. He also suggests a new classification of schizophrenias : the unsystematic schizophrenias (affect paraphrenia, scizophasia, periodic catatonia) and systematic schizophrenias (the catatonic forms : parakinetic, manic, proskinetik and 2 forms of speech catatonias). The hebephrenias he discusses under 4 forms : the silly, the confused, the shallow and the autistic. Of the paranoid forms of schizophrenia the author describes 6 classes : the hypochondriac, the phonemic, the incoherent, the fantastic, the confabulous and the expansive, besides their various combinations. The final chapter of this provocative work is dedicated to statistics : the ages and sex distributions of the phasic and cycloid psychoses and schizophrenias and the hereditary factors in these conditions.

HIRSCH L. GORDON, M.D.,
Yeshiva University Graduate School.

THE LIFESPAN OF ANIMALS. Ciba Foundation Colloquia on Ageing, Vol. 5. Edited by G. E. W. Wolstenholme and C. M. O'Connor. (Boston : Little, Brown and Co., 1959, pp. 324. \$9.50.)

As stated in the preface, "This volume contains the proceedings of the fifth colloquium on ageing, and also a combined index to this and the previous four volumes." Fourteen papers are presented, the first two dealing with humans and the rest with cattle, horses, rats, birds, fishes and insects. Most of the papers present carefully worked out statistical material, some of which is of a highly technical na-

ture and requires considerable knowledge of statistics to evaluate. Each paper is followed by the discussions which took place at the meeting with sometimes as many as 13 different discussants participating. A great deal of very interesting material is presented in these discussions and one gets a very personal feeling of listening to a number of persons who have spent years in this sort of work and who are acknowledged authorities on the subject. The book can be recommended as having presented in excellent fashion some "basic research relevant to the problems of the Ageing."

K. M. B.

NEUROPSYCHOPHARMACOLOGY — PROCEEDINGS OF THE 1ST INTERNATIONAL CONGRESS OF NEUROPSYCHOPHARMACOLOGY, ROME, 1958. Edited by P. B. Bradley, P. Deniker and C. Radouco-Thomas. (New York : Elsevier Press, 1959, pp. 727. \$27.00.)

This volume comprises all the papers presented at the First International Congress of Neuropsychopharmacology, Rome, 1958.

It is divided into two parts. The first part is devoted to the Symposia and Plenary Sessions, and is of particular interest not only because of the topics covered, but because of the inclusion of the discussions held, which, having been well edited prior to publication, are better organized and more lucid than most. The second part embodies the individual papers presented and discussions are not appended.

The scope of this volume is extensive, ranging from analysis and methods of drug-induced behavioral changes in man and animals, through social aspects of psychopharmacotherapy to clinical papers on treatment, clinical trials and frankly scholastic papers dealing with classification and delimitation of mental disorders.

Of special interest is the paper by Hoff and Arnold of Vienna on methodology of drug-induced mental alterations in humans. Mayer-Gross makes a lasting contribution in his paper regarding evaluation of results of experimental or therapeutic drug administration. His conclusion that more attention should be paid to techniques of observation and recording rather than to the technique of research design echoes what we have frequently observed—that excellent research designs are rendered worthless either by the application to poorly selected samples or by inaccurate compilation and recording.

It is not possible to comment on individual papers, but this reviewer feels that most are of excellent quality and certainly contributory to

better understanding of psychopharmacology. Data not generally available on known and experimental drugs, such as the pharmacology of psilocybin, described by Cerletti, or neurochemistry, like the intriguing description of effect of triptomine derivatives on dog behavior under brain-stem stimulation, presented by Sai-Halasz and Endroczy, are found in this book.

Of primary interest, and most essential for serious researchers in this field, this book contains such varied topics as to render it of marked interest to clinical psychiatrists and to members of associated or collateral professions.

ANTHONY SAINZ, M.D.,
Director, Division of Research,
Marcy State Hospital, N. Y.

SOURCEBOOK IN PSYCHOLOGY. Introduction by James Drever, M.A. (Edinburgh). (New York: Philosophical Library Inc., 1960, pp. 335. \$6.00.)

A collection of readings from prominent authorities dealing with a wide range of topics in the general fields of psychology are here usefully brought together in a single volume.

On the title page particular attention is directed to the Introductory Reading Guide which is written by Professor Drever and titled *The Subject-Matter of Psychology*. It is hardly a reading guide insofar as the contents of the book are concerned, but is rather, in the main, an elementary statement about psychology adapted apparently for the general reader or for junior students. Curiously enough however it goes into theoretical psychopathology and even into psychotherapy and lists also other current treatment methods pertinent to mental illness as such, but hardly relevant to introductory psychology. Moreover a book of this kind requires no reading guide as each contribution is accompanied by a brief introductory note.

There are 31 contributions grouped under three general and somewhat arbitrary headings: 1. *The Study of Behavior*; 2. *The Maturing Mind*; 3. *The Study of Personality*.

Professor Boring of Harvard leads the series with some basic definitions and indicates the influence of behaviorism and Gestalt psychology on subsequent developments. The 30 items that follow are representative statements of eminent and preeminent leaders and innovators

in the field of psychology. Here you will find the conclusions of Germany's great biologist Ernst Haeckel as set forth in his world-famous book *Riddle of the Universe*. Herbert Spencer discusses the behavioristic side of the emotions. Charles Darwin (*The Descent of Man*) introduces animal psychology by showing the similarities of the mental reactions of the human and of other animals, thus disturbing the equilibrium of the rigid ultraists who make man, not the "lower" animals, inheritors of heaven. Freud revives and re-emphasizes the role of the unconscious side of the psyche in accounting for the psychology of errors (the "Clown Prince," the "battle-scared veteran," etc.).

Sir Cyril Burt, educational psychologist, advises on the mental development of children; and Hobart Mowrer, research professor of psychology, University of Illinois, discusses discipline in the training of children.

Here in a lecture before the Society for Psychological Research, Carl Gustav Jung details the psychology of the primitive and still widely held belief in spirits. Norman Cameron, professor of psychiatry at Yale, deals with "behavior psychology," role-taking and communications.

James Drever, many years professor of psychology at Edinburgh and presumably largely responsible for the compilation of this book,¹ deals with the psychological aspects of the penal system as set forth in his presidential address before the section on psychology of the British Association in 1926.

Happily included in the collection is William James' eloquent and oft-quoted chapter on *Habit*.

In the section on personality studies, Sir Cyril Burt discusses individual differences; Watson treats of man's adaptability to his work; Kretschmer sets forth his classification of types based on *Physique and Character*. Among other contributors, Tredgold covers industrial relations; Vernon and Parry, the use and methods of psychological testing.

A useful feature of this work is an appendix in which are given biographical notes, alphabetically arranged, of each of the contributors.

C. B. F.

¹ Professor Drever states that his son who succeeded him in the chair of psychology in the University of Edinburgh prepared the introduction to this book.

THE ESSENTIALS

When I get a little money I buy books; and if any is left I buy food and clothes.

—ERASMUS

IN MEMORIAM

DR. ARTHUR H. RUGGLES

1881-1961

Arthur H. Ruggles has left us, but we are not entirely bereft because our legacy includes a host of fond associations, of examples of devotion to his field, of friendship at its best, of good humor, of sterling integrity, originality and imagination.

Dr. Ruggles was born in Hanover, New Hampshire, January 26, 1881, the youngest of five children, into an atmosphere of learning and devotion to public welfare that contributed clearly to shaping his character. His father, Edward Ruggles, was Professor of Romance Languages at Dartmouth and his maternal grandfather was treasurer of that college. His mother was Charlotte Blaisdell Ruggles. His older brother, a lawyer, became a judge in Jamaica Plains, Mass. His other brother was an engineer. His two sisters married Dartmouth men. One of them, Mrs. Helen R. Hodgkins survives him.

While a student at Dartmouth, from which he graduated in 1902, Arthur Ruggles was a member of the Delta Kappa Epsilon fraternity. Later he was inducted into Phi Beta Kappa. He took part in many extra-curricular activities including the management of the football team. This early pattern of participation in community affairs continued throughout his life. He served as a trustee and gave generously otherwise of himself to his college. In recognition of his leadership in the field of psychiatry he received an honorary Doctorate of Science in 1927 (his 25th reunion) from his alma mater, and also in 1929 from Brown University and in 1948 from Rhode Island State College, now the University of Rhode Island.

In 1906 Dr. Ruggles received his medical degree from Harvard. Prior to this he had already revealed his life interest in psychiatry by spending two of his summers at the Danvers (Massachusetts) State Hospital. He rounded out his medical training as an intern on the staff of the Rhode Island Hos-

pital 1907-09. In 1909 he was invited to join the staff of Butler Hospital in Providence, where except for short periods he served for the rest of his life. This was far from the narrow experience that it might seem, for so well organized was his administration that he was able to assume many other local, state, national and international tasks along with his regular work. However his interest throughout life focused more on the psychodynamics of mental disorder. In 1912-13 he took postgraduate work at the University of Munich under Professor Emil Kraepelin.

During World War I, he was in charge of Base Hospital No. 214 in France with the rank of Major and was psychiatrist to the 2nd Division. He returned to Butler at the end of the war, and in 1922 he was appointed successor to G. Adler Blumer on the latter's retirement from the superintendency of that hospital, serving as such until 1948 when he became Superintendent Emeritus and consultant. For a short period he was on leave from Butler to organize the Mental Hygiene Department at Yale, where he was appointed Professor of Clinical Psychiatry. He taught at Dartmouth College, also at Brown, where he served as Student Mental Health Consultant in 1920. In 1931, without relinquishing his responsibility for Butler Hospital, he planned, organized the construction of and until 1943 administered Bradley Hospital, the last two years as Executive Vice-President. This is a small hospital in Riverside, R. I., founded by Mr. and Mrs. George Bradley for children with neurological and emotional disorders. In 1943 he became president of its Board of Trustees. He was Chairman of the Psychopathic Department of the Charles V. Chapin Hospital and established a Child Guidance Clinic in the local schools in 1916.

Dr. Ruggles served on many local and State Boards, including in later years the Council of Social Agencies and the State

Parole Board. He was on the Advisory Council of the State Department of Social Welfare. He served as president of his local and state medical societies. He served both Florida and Massachusetts at the request of their respective governors by surveying their state institutions. The care with which he performed these tasks resulted in some significant reforms. He was a member of the Board of Deacons of the Congregational Church in Providence and was accorded local honors for his many public services.

Nationally, he served as President of the National Committee for Mental Hygiene and of the 1st International Congress on Mental Hygiene and as a delegate from the United States to the Second International Congress. He served as Secretary and Treasurer 1938-41 and presided over the American Psychiatric Association in 1943¹ after rendering invaluable service in a critical period of its existence. He was one of the founders of the Group for the Advancement of Psychiatry. He served on the Advisory Council on Research of the United States Public Health Service. He represented the APA along with Dr. Edward A. Strecker and Dr. Frederick W. Parsons in World War II in an advisory capacity to government agencies and was called on by Secretary of War Stimson as a consultant. In this capacity he tied together the efforts of the APA and the National Committee for Mental Hygiene.

Dr. Ruggles contributed abundantly to the professional literature. In 1951 he delivered the Thomas W. Salmon Memorial lectures on the subject: The Place and Scope of Psychotherapy.

¹ July 1943 issue of the Journal contains Dr. Ruggles' Presidential Address and photograph.

In 1948 Dr. Ruggles suffered a setback from which he never fully recovered. As a result of a severe respiratory infection he suffered cardiac damage which forced him to carefully budget his activities. For this reason he had to relinquish many of his outside responsibilities that required traveling, but by his wise planning he was able to continue to give great service to his community, and counsel on national matters to those visiting him. He especially regretted his inability to serve actively as Chairman of the Research Committee on Schizophrenia, a program conducted by the Scottish Rite through the National Association for Mental Health. Still so distinctive was his leadership that he was retained in an honorary capacity in this and many other of his associations.

Dr. Ruggles always had a critical scientific conscience behind his clinical work. While he could accept common sense as a matrix for the application of science, he demanded that it be sound. "Mumba-rumba" was his way of characterizing pseudo-scientific work.

Dr. Ruggles' domestic life was prematurely limited by the loss of his wife, *nee* Hazel M. Wheeler, in 1939, whom he had married on April 22, 1914. His devotion to her was revealed often to those who knew him well whenever family functions came up for discussion. To them came two children, Arthur Jr., and Ann.

Those of us who can credit ourselves with being his contemporaries know how much our juniors have missed by not knowing Arthur Ruggles also, however much they have gained from him as a heritage.

WILLIAM NOBLE KELLER, M.D.

" 1875-1960

The character and personality of William N. Keller never seemed to fit into any set mould. Yet, his accomplishments well typify the heights attained by leading mental hospital superintendents of the first half of the twentieth century. Throughout his adminis-

trative career he could always be found in the van of the group of medical entrepreneurs who were not psychiatrists but who entered administration from the main stream of medicine to help tear down the walls of isolation of America's mental hospitals. Dr.

Keller's credo was action—direct action, independent action, persistent action—so that he was constantly immersed in turmoil, ferment and excitement with the result that accomplished facts become significant accomplishments. Not only did Dr. Keller have an extraordinary impact on physicians with whom he served, who are largely located in the Pacific Northwest, but also his influence on mental hospital administration spread far from the Western State Hospital he loved.

William N. Keller was born February 26, 1875 at Council Bluffs, Iowa, the son of Samuel L. and Elizabeth Noble Keller. After attending the common schools of Council Bluff he was graduated from Princeton University in 1894. He was graduated from Rush Medical College in 1899 and interned at Cook County Hospital with an emphasis on surgical training under John B. Murphy and Frank Billings. The latter secured Dr. Keller an appointment as Attending Surgeon for the Denver Rio Grande Railroad Hospital at Salida, Colorado where he served from 1900 to 1905. He became Chief Surgeon for the Northern Pacific Hospital in Tacoma, Washington in 1905 and served as Surgeon for the Chicago, Milwaukee and St. Paul Railroad in Tacoma from 1906 until 1914, simultaneously conducting a vigorous private practice of surgery. He was appointed Superintendent of Western State Hospital, Fort Steilacoom, Washington in 1914, resigning in 1922, and resuming surgical practice in Tacoma. During World War I he took a year's leave of absence, serving as a Major in the Medical Corps of the United States Army. He was reappointed to the superintendency of Western State Hospital in 1933 and remained in that post until he retired in 1949 at age 74.

During years of private medical practice Dr. Keller was on the staff of the St. Joseph's Hospital and Tacoma General Hospital and served as Chief of Staff of Pierce County Hospital, all in Tacoma. He was a member of the Pierce County Medical Society, serving one term as President. He was a member of the Washington Society for Mental Hygiene, National Committee for Mental Hygiene (Honorary Member), Fellow of the American Medical Association, a Charter Member and Life Fellow of the North

Pacific Society of Neurology and Psychiatry, Fellow of the American Psychiatric Association, Life Member and Fellow of the American College of Surgeons and a Diplomate of the American Board of Psychiatry and Neurology.

All of Dr. Keller's psychiatric career was spent in command of Western State Hospital, which he viewed as a vital, dynamic institution, with a distinct personality of its own. Having had no cloistered psychiatric training the thought of the hospital being isolated and apart from the community never entered his mind. He developed an extraordinary *esprit de corps* in patients, employees and professional staff, which led to a natural participation in all spheres of community activity. Many of the popular community-hospital innovations of the 1950's were put into effect or advocated by Keller as early as the 1930's.

In early years of private practice Dr. Keller was very active in the social and business life of Tacoma. His contacts were legion. He served on governing boards of banks, corporations and service organizations, as well as actively participating in the real estate development of the area. By the time he became enmeshed with the challenges of hospital administration he had developed diverse and catholic interests. Thus, there was no phase of hospital operations with which he did not become intimately familiar over the years; from clinical psychiatry to farming, from ward management to architecture, from purchasing to personnel. As would be expected, he could not abide the notion that the development of one of the nation's finest dairy herds indicated a disinterest in the welfare of patients and their clinical progress. That some other superintendent was cursed with poor farm land or was incapable of exploiting good land for profit, was considered by Keller a faulty argument that he should avoid usefully integrating farming with other hospital activities.

Perhaps nowhere was Dr. Keller's capacity to get to the bottom of things better demonstrated than in the manner in which he developed Western State Hospital's building program. In the public works days of the 1930's he practically rebuilt the major part of an old Kirkbride hospital plant and

established a master plan which has been followed closely since his retirement. He even succeeded in building a new home for nurses in the middle of World War II. His most spectacular building coup occurred a few years before retirement when he detected loose words in an appropriation title for a new building to cost several million dollars. He used the entire appropriation to build the concrete frame and the roof of a building which ultimately housed 400 patients. In a following session an austerity minded legislature had no alternative but to appropriate several millions in addition to complete the structure. In this way was a dreadful overcrowding of patients relieved.

After a long and vigorous campaign Dr. Keller succeeded in 1948 in building a research institute as an integral part of Western State Hospital. He held the idea that while pure research was important elsewhere, the best help to patients of his hospital would be an integrated operation with most members of the active professional staff engaging in research to some extent.

Partisan political interference in mental hospitals was forever publicly damned by Dr. Keller. He felt that overt manifestations of political activity were to be shunned and that such detracted from the dignity of medicine. Yet, he was always a political realist in respect to the bureaucratic and

governmental strife which constantly pervades mental hospitals. In this sphere he operated with a brilliance seldom seen. He was a determined and courageous adversary who used all his skill and knowledge of human events to advance the welfare of Washington's mentally ill, playing off one pernicious force against another and patiently outwaiting those which could not be met head on.

One trait eternally to Dr. Keller's credit was an inclination to encourage fellow psychiatrists to enter mental hospital administration. In a convivial setting he loved to pass on in an academic manner the lessons of his many years' experience. The things he had to teach don't come in books and mental hospital administration has been advanced greatly by his willingness to share the fruits of his experience and to stimulate the imaginations of his colleagues.

William N. Keller died January 14, 1961 in Tacoma. He is survived by his wife, the former Mabel Lawrence, a son, William, a daughter, Elizabeth and four grandchildren. For the golden years of his professional life there are no more appropriate words than those he had engraved over the entrance to Western State Hospital, "Dedicated to Mental Health."

Charles H. Jones, M.D.

SUCCESS

Let us be thankful for the fools. But for them, the rest of us could not succeed.

—MARK TWAIN

MODERN MAN

The whole prospect and outlook of mankind grew immeasurably larger and the multiplication of ideas also proceeded at an incredible rate. This vast expansion was unhappily not accompanied by any noticeable advance in the stature of man either in his mental faculties or his moral character. His brain got no better ; but it buzzed more.

—CHURCHILL (1915)

THE AETIOLOGY AND TREATMENT OF CHILDREN'S PHOBIAS :

A REVIEW

S. RACHMAN, AND C. G. COSTELLO¹

The past few years have seen the establishment of two conflicting views regarding phobias in children. Most workers in this field, psychiatrists and psychologists, are influenced to a greater or lesser extent by either the psychoanalytic theory or the behavior theory in their approach to the subject of phobias. For this reason we have restricted our review primarily to these two theories.

PSYCHOANALYTIC THEORY

The psychoanalytic theory of phobias derives very largely from Freud's case history of Little Hans(14) which was published in 1909. The essentials of the phobic theory were presented in this paper and appear to have undergone little change in the past 50 years.

The theory states that the basis for phobic disturbances is the Oedipus Complex. The child desires to possess the mother sexually and is jealous and hostile towards the father. The child fears his father because of these hostile wishes and, in particular, dreads castration. The fear of the avenging father is then projected onto some external and formerly innocuous object. The outbreak of the phobia is generally preceded by a period of privation and/or intensified sexual excitement.

This development of phobias may be analysed into the following components.

1. The child "is fixated at the oedipal or pre-oedipal level"(22).

Freud(11) states that psychoanalysis has "often showed that animal (phobic object) was a substitute for the father, a substitute on to which the fear of the father derived from the Oedipus complex has been displaced."

(1a) The child has a sexual desire for the mother.

This aspect of the theory is stressed in

¹ Institute of Psychiatry, Maudsley Hospital, University of London, Eng.

the case of Little Hans(14). In a discussion on the psychogenesis of agoraphobia in childhood, Abraham(17) illustrates Freud's theory by referring to case material: The phobic child had "an incestuous wish for sexual possession of her (the mother)."

(1b) The child is jealous of, and hostile to, the father.

In the discussions by Abraham mentioned above, he also makes explicit the child's hostility to the father—he had "a death wish against his father."

2. The child fears the father.

Freud(12) states that "the animals which play a part in the animal-phobias of children are generally father-substitutes."

He also says that "the instinctual impulse subjected to repression here (in animal phobias) is a libidinal attitude to the father, coupled with a dread of him. After repression this impulse vanishes out of consciousness"(15).

(2a) The child has castration fears.

The anxiety experienced by the child when he is confronted by the object of his phobia is a danger signal set off by his ego and the danger which is being signalled in this way is invariably the danger of castration(13).

And again, "the fear in zoophobia is castration anxiety on the part of the ego"(13).

3. The fears of the father and of castration are projected onto a neutral external object.

Castration anxiety, states Sarason, *et al.* (26) results in

the displacement or projection of the dangerous combinations upon an external (previously innocuous) object or situation. After this occurs the original castration anxiety is elicited by a different object and therefore is expressed only in a distorted form.

In Freud's words(9) "... castration anxiety is given another object and a distorted expression—namely that of being bitten by a

horse . . . instead of being castrated by the father."

4. The onset of the phobia is often preceded by a period of privation and/or sexual excitement.

"An increase in sexual longing, fear or guilt, reactivates the oedipal or pre-oedipal fear of sexual injury to the mother . . ."
(22).

Freud(14) attaches importance to this precipitant in the Little Hans case as does Bornstein(2) in the case of Lisa.

5. The onset of the phobia is generally preceded by an anxiety attack which is associated with the phobic object.

Freud(13) states that "a phobia generally sets in after a first anxiety attack has been experienced in specific circumstances such as in the street or in a train or in solitude." Similarly, Abraham is quoted as stating that "in general, the phobic reaction to a specific object or situation becomes established only after the child has experienced an anxiety attack while interacting in some way with the particular object or situation"(26). The initial anxiety attack itself however is produced by castration fears. "The phobic process begins when the ego recognizes the danger of castration and consequently gives a signal of anxiety"(26).

6. Phobias only develop in people with disturbed sexual adjustments.

Freud(10) states that, "the main point in the problem of phobias seems to me that *phobias do not occur at all when the vita sexualis is normal*," (original italics).

He says further, "My theory is only to be gainsaid by evidence of phobias occurring together with a normal *vita sexualis*."

Watson and Rayner's(31) laboratory demonstration of the development of a phobia in little Albert (see below) must bring into question 5 of the 6 elements of the psychoanalytic theory as does the evidence discussed in the works of Wolpe(32), Eysenck (7, 8) and Jones(19). Point 5, however, approaches close to the learning theory account of phobias described below. The learning theory position is that the onset of the phobia is not merely preceded by an anxiety attack which is associated with the phobic object but that the anxiety attack

is generally the major cause of the phobia. More generally, Ellis(6) argues that

the vague, suppositional and multi-interpretive terms in which the theoretical framework of orthodox analysis is usually stated make it almost impossible to test its concepts by normal psychological methods of investigation.

And we may add, it also makes it almost impossible to appraise the internal consistency and logic of psychoanalytic theory—as a theory.

Ellis(6) has criticised the unscientific nature of psychoanalysis and emphasizes the inadequacies and confusion of the theory, the unreliability of the supportive evidence, the failure to submit any part of the theory or practice of psychoanalysis to acceptable scientific test. One of Ellis's most insistent complaints is against the rampant speculation so common in psychoanalysis. As we hope to demonstrate below, one of Ellis's comments on a passage of Freud's writings seems in fact to be applicable to a large body of psychoanalytic literature. He remarks that, "the ratio of speculative statements to empirically adduced facts . . . is slightly overpowering."

PSYCHOANALYTIC EVIDENCE

Clinical evidence serves a double purpose in psychoanalysis. It is used in order to construct the theory and also to support the theory. Some serious deficiencies present in psychoanalytic case material have been discussed in a critical examination of Freud's treatment of the famous Little Hans case (33). Although the criticisms which we offer here may all be applied equally well to the Little Hans case, we have restricted our comments to other well-known case histories in order to emphasise that these flaws are the rule rather than the exception.

ELABORATION

Bornstein(2) presents an account of a girl of 2 yrs. 4 mths. who developed a phobia of lying down. At one point, Bornstein writes, "She was asked directly what she really had to fear in bed. She replied with a recital of misdeeds having the character of severe self-reproach." The following is an example of what the child said, "See

cup ow." Bornstein states that this means ("translated into the language of the adult") "See the cup is broken, has pain (ow) and it is my fault." We suggest that this is an elaboration, particularly the claim that the child felt at fault.

Later we read that the child used to masturbate by rubbing her legs together. Then, the mother reported, she stuck diapers or table napkins between her legs. Bornstein comments, "As if wishing to demonstrate that her genitalia were not 'Ow,' not damaged, that in other words she possessed a male genitalia."

A more extensive elaboration is given in an account of one of the child's dreams. The child reported the dream thus; "Opa dudu." Bornstein gives as a direct literal translation "Grandpa naughty naughty," but writes also that it "meant that her grandfather had appeared to her in a dream and had either threatened or spanked her." Later the dream was apparently better understood and Bornstein writes, "The little girl's favourite game before she was sick had been the 'Kuckuck game.' This consisted in hiding and then calling 'Kuckuck' which the child who still spoke very imperfectly often used to pronounce 'Duduck' or really almost 'Dudu.' The dream therefore said 'Grandfather is hiding, has gone away.'"

Further elaborations are given in connection with two incidents. (a) The grandfather on one occasion when out with the child had gone behind a tree and urinated. (b) The grandfather had taken the child's mother away for a short period in order to look after the sick grandmother. "Opa Dudu" finally means "If I am not good mother will be taken away by grandfather." But over and above this, it also expressed the wish that "her grandfather would play Dudu again—that is disappear and expose his penis." We suggest that this also reveals a tendency towards over-elaboration.

SUGGESTION

Schnurmann(27) gives an account of a girl, Sandy, who developed a dog phobia at the age of 2 yrs. 5 mths. At that time (1944) she was in the Hamstead Nursery. One night she had a nightmare: "She told the nurse a dog was in her bed." Schnurmann comments later that,

As Sandy had up to then not shown any special interest in dogs it seems strange that in the dream the dog was invested with great significance. An explanation may be found in the following facts: "When the nursery children were taken out in a group an encounter with a dog was usually met by some kind of emotion on the part of the other children. The fear of dogs at night continued for the next three nights. Statements like "Out, out, out, doggie coming" were made. On the fourth night, "Sandy undertook a thorough inspection of her genitals. She was deeply absorbed in this activity and did not take any notice of our presence (two therapists). The worker told her that everything was all right there and that all girls looked like that.

The next day, "On the way to the nursery some of our children started to play with a strange dog. I explained to them that he might bite if they frightened him." It is noteworthy that it was only from this time that the child showed signs of fear of dogs in the street. The main point, however, is that it was only after the worker had drawn the child's special attention to her genitals and after the worker had suggested that the dog might bite, that Sandy herself began to talk about biting. Two nights later Sandy said to the worker, "Bite Annie Bite."

"I asked 'Where bite?' She lifted her nightie pointed to her genitals and said, 'There bite.'"

There was a considerable amount of talk about biting for the remainder of the therapy which enabled the therapist to conclude that, "In the nightmare—as it became clear in Sandy's subsequent behaviour and remarks—a dog was assaulting Sandy in her bed, injuring her genitals, i.e., biting off her penis."

It is also noteworthy that after Sandy's attention had been drawn to the 'rightness' of her genitals she became quite concerned about the rest of her body and clothes—fingers, legs, coat, hat. They all became penis symbols by displacement apparently.

It is felt that, after having given the child the idea that genitals are all right (or all wrong) and also warning her that dogs bite, to regard her subsequent concern with these ideas as confirming the analysis is unsatisfactory and not convincing.

INVERSIONS AND NON-ACCEPTANCE

A common feature of psychoanalytic case reports is the refusal to accept the patient's accounts and to attach instead a reversed meaning to his testimony. The tendency is clearly illustrated in the case of Frankie, aged 4½, reported by Bornstein(3). For example, the boy reported a dream in which he, the room and two other persons were falling down. Bornstein comments, "Actually, the emphasis on 'going down' was a representation of its opposite being lifted up."

We feel then the psychoanalytic theory of phobias is inadequate for the following reasons: 1. The theory is complex and loosely formulated. 2. The evidence is not related clearly to the theory by means of predictions from the theory. 3. The evidence is manipulated through over-elaboration and inversion to fit into the theory and sometimes the patient himself is manipulated by suggestion so that his behavior may fit into the theory.

We will now proceed to an account of an alternative theory—Behavior Theory—which has been presented to account for the development and treatment of phobias.

A BEHAVIOR THEORY OF PHOBIA

The past decade has seen the growth of a new theory of neurotic behavior which has been developed from learning theory. Expositions of the general theory are provided by Wolpe(32) Eysenck(7, 8), Jones(19).

The position adopted by this theory is that neurotic behavior is acquired. The process of acquisition implied in the theory is derived from Hull's system.

Wolpe(32) defines neurotic behavior as "any persistent habit of unadaptive behavior acquired by learning in a physiologically normal organism." Anxiety is "usually the central constituent of this behavior, being invariably present in the causal situations."

In similar vein, Eysenck(7) postulates that, "neurotic symptoms are *learned patterns of behavior* which for some reason or another are *unadaptive*," (original italics). Neurotic behavior patterns persist paradoxically, because they are unpleasant. Having acquired an unpleasant association and re-

action to a particular stimulus or situation, the person will tend to avoid exposure to these noxious circumstances. As learned patterns of behavior can only be extinguished by repeated unreinforced evocations, the tendency to avoid the noxious situation often precludes the possibility of a spontaneous disappearance of the neurotic behavior. Furthermore, if the person does come into contact with the noxious stimulus he generally responds by withdrawing. This withdrawal is followed by a reduction in anxiety and will reinforce the avoidance behavior mentioned above. This then is what Eysenck(7) refers to as "the vicious circle which protects the conditioned fear response from extinction."

As is the case in all learned responses, neurotic reactions are subject to stimulus generalization. That is, a range of stimuli similar to the original noxious stimulus may also evoke the neurotic reaction.

It should be noted also that neurotic symptoms may under certain circumstances result "not from the learning of an unadaptive response, but from the failure to learn an adaptive response"(19). An instance of this type is enuresis nocturna.

The experimental evidence which supports the behavior theory of neurosis is discussed in Wolpe(32), Eysenck(7, 8), Jones(19).

In terms of the behavior theory, *phobias* may be regarded as conditioned anxiety (fear) reactions.

Any neutral stimulus, simple or complex, that happens to make an impact on an individual at about the time that a fear reaction is evoked acquires the ability to evoke fear subsequently. If the fear at the original conditioning situation is of high intensity or if the conditioning is repeated a good many times the conditioned fear will show the persistence that is characteristic of *neurotic* fear; and there will be generalization of fear reactions to stimuli resembling the conditioned stimulus(33).

The experimental evidence supporting this view of phobias is discussed in Wolpe(32) and Wolpe and Rachman(33) and is derived from studies of the behavior of children and of animals. The classical demonstration of the development of a phobia in a child was provided by Watson and Rayner

(31) in 1920. Having first ascertained that it was a neutral object, the authors presented an 11-month-old boy, Albert, with a white rat to play with. Whenever he reached for the animal the experimenters made a loud noise behind him. After only 5 trials Albert began showing signs of fear in the presence of the white rat. This fear then generalized to similar stimuli such as furry objects, cotton wool, white rabbits. The phobic reactions were still present when Albert was tested 4 months later.

The process involved in this demonstration provides a striking illustration of the manner in which phobias develop and may be represented in this way :

1. Neutral Stimulus (rat) → Approach R
2. Painful noise stimulus (UCS) → Fear (UCR)
3. Rat (CS) + noise (UCS) → Fear
4. Rat (CS) → Fear (CR)
5. Rabbit (CS¹) → Fear (GCR)
6. Cotton Wool (CS²) → Fear (GCR)

The essentials of the theory may be summarized in 6 statements.

1. Phobias are learned responses.
2. Phobic stimuli, simple or complex, develop when they are associated temporally and spatially with a fear producing state of affairs.
3. Neutral stimuli which are of relevance in the fear-producing situation and/or make an impact on the person in the situation, are more likely to develop phobic qualities than weak or irrelevant stimuli.
4. Repetition of the association between the fear situation and the new phobic stimuli will strengthen the phobia.
5. Associations between high intensity fear situations and neutral stimuli are more likely to produce phobic reactions.
6. Generalization from the original phobic stimulus to stimuli of a similar nature will occur.

Each of these 6 statements is based on experimental evidence and would also appear to be consistent with clinical experience(32, 8). All are supported by Wolpe's experiments(32) and evidence for specific statements is provided by Liddell(25), Jones(19), Watson and Rayner(31), Eysenck(8) and Gantt(16) among others.

It can be legitimately argued in fact that these propositions are supported by the full weight of almost all the evidence accumulated in research on the learning process.

BEHAVIOR THERAPY

The essence of Behavior Therapy is clearly deducible from the theory. If neurotic behavior is acquired (learned) it should be amenable to 'un-learning' in a manner similar to that whereby non-neurotic acquired behavior is extinguished. The two major decremental processes in learning are inhibition and extinction. Numerous therapeutic procedures based on these processes have already been developed(32, 8) and additional techniques are now under investigation. The indications are that these methods are successful in a variety of neurotic disturbances(7, 8, 32), but a definitive conclusion must be postponed until a properly designed and controlled experimental test has been conducted. Such an investigation admittedly poses serious and difficult practical problems but on theoretical grounds, behavior therapy is eminently suited for such an investigation. The hypotheses and procedures are clearly defined and manipulable and a satisfactory study can be expected to provide a relatively unambiguous answer.

Most of the case-reports available to date which deal with the treatment of children's phobias involve the use of Wolpe's 'inhibitory therapy.' He defines the principle of reciprocal inhibition psychotherapy :

If a response antagonistic to anxiety can be made to occur in the presence of anxiety-evoking stimuli so that it is accompanied by a complete or partial suppression of the anxiety responses, the bond between these stimuli and the anxiety responses will be weakened(32).

The method may be illustrated by referring to some actual case reports which we summarize briefly here.

A 3-year-old boy, Peter, evinced fear of white rats, rabbits, fur, cotton wool and other stimuli along this continuum. He was treated by Jones(21) using de-conditioning methods. It was decided to work on the rabbit phobia as this seemed to be a focus of Peter's fears.

Peter was gradually introduced to contacts with a rabbit during his daily play period. He was placed in a play group with 3 fearless children and the rabbit was brought into the room for short periods each day. Peter's toleration of the rabbit was gradually improved. The progressive steps observed in the process included: "rabbit in cage 12 feet away tolerated . . . in cage 4 feet away tolerated . . . close by in cage tolerated . . . free in room tolerated . . . eventually, fondling rabbit affectionately." Another measure employed by Jones involved the use of feeding responses. "Through the presence of the pleasant stimulus (food) whenever the rabbit was shown, the fear was eliminated gradually in favor of a positive response."

Using these techniques Jones overcame not only Peter's fear of rabbits but all the associated fears. The follow-up of this case showed no resurgence of the phobia.

Lazarus and Rachman(24) describe the treatment of a 14-year-old boy who had suffered from a fear of hospitals and ambulances for 4 years. The phobia had developed after the prolonged illness and suffering experienced by his mother. She had been taken from the house several times by ambulance and spent over a year in hospitals.

The boy was first trained to relax. Hierarchies of disturbing situations concerning ambulances and hospitals were then constructed, ranging from mildly upsetting to extremely upsetting items. The lowest item in the ambulance hierarchy for example, was a mental image of a derelict ambulance in a scrap-yard and the highest item an image of sitting beside the driver in a moving ambulance. The therapist then slowly worked up the hierarchies desensitizing each item by relaxation responses. After 10 interviews, the boy was much improved and was able to visit a hospital. Four months later he was still quite well.

The third case, reported by Lazarus(23), deals with an 8-year-old boy who developed a fear of moving vehicles 2 years after having been involved in a motor accident. Initially the therapist rewarded the boy whenever he made a positive comment concerning vehicles, by giving him a piece of his favorite chocolate. By the third interview the boy was able to talk freely about all types of moving vehicles. Next a series of "accidents" with toy motor cars was demonstrated. The boy, John, was given chocolate after each accident. Later John was seated in a stationary vehicle and slow progress (with chocolate feeding reinforcements used at

each point) was made until John was able to enjoy motor travel without any anxiety.

Lazarus also describes the successful treatment of a case of separation anxiety and a case of dog-phobia. Case reports describing the treatment of phobias in adults are provided in Eysenck(8).

REINTERPRETATION OF PSYCHOANALYTIC CASES

A further advantage of behavior theory is that it can account for and incorporate a good deal of evidence presented by psychoanalysts. We will illustrate this with several examples from the literature.

A number of psychoanalysts when discussing school phobia have stressed the importance of getting the child back to school early. Eisenberg(5) writes, "In general, the longer the period of absence from school before therapeutic intervention is attempted the more difficult treatment becomes." In explanation he writes, "Left at home the patient . . . is reinforced to persist in infantile manoeuvring by the 'success' of his efforts." This point has also been stressed by the workers at the Judge Baker Guidance Center(4, 18, 29, 30). No attempt is made, however, to incorporate this important aspect of therapy in the psychoanalytic theory. This therapeutic procedure is in a sense even contradictory to the theory insofar as it is symptom-oriented. This failure to account for important data by means of the theory can be added to the list of deficiencies above.

The importance of the early return to school can be accounted for by the behavior theory of phobias in the following manner:

As learned responses (including fear) can only be abolished by extinction or inhibition, no reduction of the school phobia can be expected to occur if the person is entirely isolated from the noxious situation. Furthermore, continued absence from school will certainly reinforce the phobic pattern. It will have this effect because of the reduction in school-anxiety which is produced when the person refrains from attending school. Like all learned behavior, phobic responses are strengthened by drive reduction, in this case, reduction of the anxiety drive.

Another aspect of therapy for school phobias has been stressed by some psychoanalytic writers. Klein(22) writes :

The child is told he must go to school every day, but does not have to stay there and does not have to attend the classroom. The child can stay in an office, assist the office staff, read or draw and can leave at any time.

This graded approach is another aspect of therapy not in keeping with the general psychoanalytic approach and not accounted for by the theory. It is on the other hand a procedure which directly follows from the behavior theory of phobias.

Though the psychoanalytic case histories referred to in this paper are long and complex, most of the data presented are taken from the analytic sessions and the phobic situation itself is seldom described adequately. For this reason it is not possible to give precise accounts in terms of behavior theory of the development and treatment of the probias reported. But one or two general observations can be made.

We referred earlier in this paper to Bornstein's case of the girl who developed a phobia of lying down(2). From the point of view of behavior theory the following points are of importance. "Training in cleanliness was begun in the sixth month. The child was held over the pot at regular hours." Towards the end of the first year, the child's grandmother took over the toilet training and apparently imposed severe measures. After the age of one year the child wet herself on very few occasions. One of these occasions was the day before her mother's return from an illness, when she wet herself several times. "The members of the household thought it probable that when this happened they said to her 'Wait until your mother hears you have wet yourself again! She won't love you any more. She will go away again and won't want to come back.'"

Bornstein comments,

We believe that she could not allow herself to lie down because she was afraid that when lying down or sleeping she would be unable to control the wish to defecate in bed . . . Moreover we know of an historical factor which had connected the motif 'incontinence' with the

motif 'not sitting' : *After her illness with diarrhoea the child could no longer sit up.*

(original italics). Bornstein is referring here to the fact that when the child was 7-months-old she had an attack of diarrhoea which left her so weak that she could no longer sit alone.

From the point of view of behavior theory the development of the phobia can be accounted for in the following way : Because of her severe toilet training the stimulus to urinate or defecate had become associated with anxiety. The association of defecation with lying down (at the time of her illness) resulted in the act of lying down also producing the anxiety response. The child then attempted to avoid anxiety by sitting up all the time.

Concerning the child's recovery from the phobia, the following observation is noteworthy :

The child on one occasion refused to resume even a sitting position in bed. As was usual she was left. She soiled herself, the bed was changed and the girl asked her mother to give her a hug which she was given. Then to the mother's astonishment the girl happily lay down in bed for the first time in five weeks.

It would seem unlikely that this one association of soiling with an accepting and affectionate response was sufficient to produce a recovery. Although we are not informed whether, after this "astonishing" result, the mother altered her attitude and behavior to her child we will assume that she used this experience in her future handling of the girl. If she continued to use affection and re-assurance to dampen the child's anxiety, such a procedure would almost certainly have brought about a reduction of the phobia.

In the case of Sandy's dog phobia(27) and Frankie's elevator phobia(3) we do not have sufficient information to give a convincing account of the development of the phobia. But we have already seen that in both cases the phobic objects were associated with fear producing stimuli. In the case of Sandy, we have the nightmare involving a dog and the therapist's warning that dogs bite. But one may be justified in asking why the child had a nightmare involving a dog

in the first place. In the case of Frankie we have the nurse's threats that she would call the elevator man to teach him not to disturb people.

Regarding Sandy's and Frankie's recovery from their phobias we again do not have sufficient information. But it is of interest that Sandy frequently encountered dogs when out walking with the therapist which would at least present an opportunity for the extinction of the fear response. Secondly Schnurmann writes that on one occasion Sandy played quite happily with a doll's pram, "I asked her whom she had covered with the blankets. She produced a dog. I said 'A doggie.' Sandy replied, 'No pussy cat.'" It is possible that further play with the toy dog would have produced some desensitization. Finally Sandy had played dogs with other children and the therapist and it is of interest that the phobia ended in the following way: "When on the way to the nursery school we met a dog who was on a lead. Sandy at first made a withdrawing movement, then she approached the dog hesitatingly. When another dog came into sight, Sandy walked directly towards him and barked." Sandy responded in other words in a manner learned while playing at being dogs.

CONCLUSIONS

Mention has been made of Mary Cover Jones's (20, 21) classic studies in which she describes her attempt to develop techniques for eliminating children's fears. The significance of this early work is only now becoming recognized. She gives an account of several methods of treatment. Four of these appear to be promising, practical and in accord with present-day learning theory. They are the methods of:

1. Direct conditioning.
2. Social imitation.
3. Systematic distraction and
4. Feeding responses.

The fruitfulness of the behavior theory approach to phobias is well demonstrated if we add to Jones' list the additional new methods which have been, or could be used in overcoming children's phobias.²

5. Systematic desensitization (Wolpe)

6. Assertive responses (Wolpe)
7. Relaxation responses (Wolpe)
8. "Pleasant" responses in the life situation—with drug enhancement (Wolpe)

In a suggestive article by Jersild and Holmes (17) further possible methods for treatment of children's fears are discussed. From their survey of parent's experiences in dealing with children's fears, Jersild and Holmes suggest these techniques (among others): Prompting the child to acquire skills which will enable him to cope with the feared situation; progressive contact with, and participation in, the feared situation; verbal explanation and reassurance; practical demonstration of fearlessness.

Some of these techniques are already employed by prevailing therapies without receiving explicit acknowledgement.

All these methods certainly provide therapists with a formidable armamentarium to begin with. What is now required is careful, thorough investigation of these methods and above all a major project to establish the degree and permanence of improvements which may be obtained by these techniques.

In the meantime, active therapists may consider conducting their own investigations of these methods when faced with children suffering from phobic conditions. Obviously the choice of the method will depend to a considerable extent on the nature of the phobia. It is worth remembering also that these methods are not mutually exclusive and it is probable that in many cases a combination of these techniques may offer the most promising approach.

A RE-EXAMINATION OF THE PHOBIC SYMPTOM AND OF SYMBOLISM IN PSYCHOPATHOLOGY

SILVANO ARIETI, M.D.¹

In spite of some important exceptions (9, 10, 14, 15), the study of phobias has been neglected recently. And yet if a symptom should be the representative of psychiatric disorders no other one could be better selected. In fact phobia or fear may appropriately represent one of the most common states of man, who in spite of, or rather, because of, his advancement and understanding, has become so aware of the precariousness of his condition as to transform danger from something to be prevented to something to be always concerned with.

The reasons why phobias have been relatively neglected in the literature are two: first; whereas phobias were seen as constituting a syndrome in themselves (called phobic state or anxiety hysteria), recently they are more frequently recognized just as symptoms of a total psychoneurotic clinical picture (and much less frequently psychotic). For the last two decades the emphasis has been on studying total syndromes rather than isolated symptoms. The second reason is the fact that after Freud's classic interpretation of phobias (8), no important diverging or supplementary hypotheses have been advanced.

Although the present writer agrees that the study of the total syndrome is more important than the study of the individual symptoms, he feels that a reexamination or reassessment of established conceptions is from time to time warranted.

THE PSYCHOLOGICAL STRUCTURE OF PHOBIAS

Freud's interpretation of phobia consists in seeing this symptom as a displacement (8). For instance, little Hans is actually afraid of his father, but in his neurosis the fear is displaced to horses. According to Freud the displacement hides a sexual threat and thus becomes symbolic of what it replaces. For instance, fear of being bitten by a horse replaces fear of castration by the hands of father.

According to the present writer, the displacement is not necessarily from one object (father) to another (horse). More than a displacement a concretization takes place. The patient may be in fearful expectancy of vague, intangible threats, which may be difficult to define or which he does not want to define or recognize: hostility from father, possibility of abandonment by mother, atmosphere of hate and resentment in the household, *etc.*

In several phobic patients the psychiatrist may easily recognize the concretization of a more general anxiety situation: fear of sexual relations hides a bigger fear in sustaining loving relationships; fear to travel hides a bigger fear of making excursions into life; fear of many little things generally hides a general state of insecurity. Odier (15), in a certain way understood this phenomenon when he wrote that "Behind the phobogenic object hides a concept, an idea, a vague intuition."

In the writer's opinion what happens in phobias is the expression of a general principle of psychopathology, *viz.*: that which cannot be sustained at an abstract level because it is too anxiety provoking, or for other reasons, is concretized. This concretization of concepts and idea-feelings is not merely the expression of a reduction to a concrete level, as Goldstein (11, 12) has described especially in organic cases, but an active process of concretization, that is, an active changing of the abstract into the concrete. For instance, before the onset of a psychosis a patient has the vague impression or feeling that the whole world is hostile toward him. After the onset of the psychosis the vague feeling becomes transformed into a concrete delusion: "They are against him" (3). Concretization reaches the point of perceptualization in hallucinations (1). For example, before the psychotic outbreak the patient had a self-effacing attitude, a pervading feeling of inadequacy and unworthiness. After the onset of the psychosis he hears voices accusing him of being a failure, a homosexual, a spy, *etc.*; that is,

¹ Address: 22 East 72nd Street, New York City 21, N. Y.

at a perceptual level he hears expressions of his own undesirability.

Phobias share with many other psychiatric symptoms the phenomenon of concretization. However, they have characteristics of their own, which have to be re-examined and reinterpreted for a more complete understanding of the phenomenon. These characteristics appear more evident if contrasted with those of delusions :

1. Whereas in delusions the threatening objects are other human beings (the persecutors), in phobias there is a dehumanization of the source of fear. For instance, bridges, cars, high buildings are frequently the phobogenic "objects." Characteristic enough is the fact that animals (horses, dogs, cats, insects) are often the phobogenic objects, but not human animals. Some human beings such as dentists, policemen, monks, may become phobogenic not because they are human but because of their role or the uniform they wear. In other words, the phobogenic object is either their role or their uniform.

2. Although the phobic patient attributes great power to the phobogenic object, he concentrates his attention on himself, that is, on the effect of the fear on himself. Whereas the deluded patient is mostly concerned with the bad qualities of the persecutor, the phobic is mostly concerned with the disturbance he will undergo if he is exposed to the danger.

3. The phobic patient retains some possibility of action within the framework of his symptomatology : he may escape the danger by avoiding the phobogenic object. In other words, it is up to him to avoid the fear-provoking situation. He is not a passive or helpless agent of persecutors, as the deluded patient.

4. Contrary to the deluded patient the phobic retains the capacity to test reality. He understands that his fear is absurd and not syntonized with the rest of his psychological functions. As a matter of fact a great part of his conflict consists in his being obligated to react in a way that he himself considers absurd.

Can these characteristics of phobias be interrelated and explained ? An attempt will be made toward a pathogenetic interrelation of the various aspects of the symptom,

but an etiological interpretation is beyond the purposes of this paper.

The fundamental mechanism in phobias is introjection, not projection. In other words, the phobogenic object is not perceived as an entity in itself but as a disturber of the organism. As I have described more extensively in other works(5), a primitive form of perception consists in experiencing the external object only as a disturber of the organism. The perception does not mirror reality. It is an inner status of disequilibrium that the external stimulus produces. What counts is the alteration of the inner status of the organism more than the mirroring of the external object(4). In phobias this primitive type of perception occurs. The phobogenic object is introjected as a disturber of the organism, not *per se*. Obviously an unrealistic quality is *projected* to the phobogenic object, but the introjection of the alleged emotional disturbance is the main characteristic and reaches exaggerated proportions.

In all forms of altered introjections or of increased emotional disturbance (for instance in depressions) appreciation of external reality is not distorted or only to a minimal degree : only the inner status is. The phobic patient retains a grasp on external reality : on the other hand the deluded patient does not. The latter does not introject pathologically ; he projects pathologically. Pathologic projection requires a transformation in cognition ; the focus is on the cognitive functions not only of the patient, but also of the external world. But the only cognitive powers in the external world are other human beings. In phobias no cognition of other people is taken into account. The phobogenic object is not considered as a malevolent being who plots the destruction of the patient ; it is seen only as a disturbing agent, not as a willed object.

It may be useful at this point to use Buber's terminology(6). In the phobic patient there is an I-It relationship between the patient and the phobogenic source ; an I-Thou relationship in the paranoid. In both cases the relationship is distorted, and seen by the patient as a one-way relationship, that is from the external object to the patient and not from the patient to the external object. As I had occasion to discuss

elsewhere(2), the pathological I-Thou relationship of the deluded is a more primitive one than the I-It pathologic relationship.

Human beings do not have merely an I-Thou relationship, but also an I-It relationship; that is, a relationship between the person and the non-human world. Many neurotic persons who have difficulties in interpersonal relations try to change the I-Thou relationship into an I-It relationship. They try to treat people as things; they depersonalize them. For instance, people become machines, sexual relations only a biological function, human relations become scientific experiments, and so on. Even the therapist becomes a therapeutic machine which renders a service. In the phobic patient the I-It relationship becomes accentuated. As I have described elsewhere (2), in the deluded patient this neurotic mechanism is absent. The patient cannot translate the personal into the impersonal. As a matter of fact one sees the opposite process: the impersonal tends to be personalized. Whatever of significance happens is never attributed to chance or to physical events (or to that particular chance which is bad luck). Almost everything is anthropomorphized and seen as a consequence of a personal will. One could object that in phobias too there is a certain kind of animism inasmuch as a special power is attributed to special situations and to inanimate things. Furthermore, animals, that is animated entities, are often phobogenic objects. This is true, but to a much more limited extent than in the psychotic patient. In phobias the phobogenic object acquires a special power only as a disturber of the organism, not as a plotting agent. Only human beings can be plotting agents.

The fact that the phobogenic object is an "It" permits the patient to retain a certain active role, that of mobilizing his defenses. In this respect the phobic differs from the psychotic and is similar to other psychoneurotic patients. The phobic defends himself with avoidance (of the danger); the hysteric with bodily impairment (so that he will not be able to face danger), the compulsive with a ritual (which, like magic, will protect him from danger).

SYMBOLIZATION

The study of phobias may help us to re-examine the general problem of symbolism in psychopathology, as phobias stand out among the most typical examples.

Since the beginning of the psychoanalytic era psychopathological symbolism has been intensely studied, but has not yet been correlated with the general symbolic process of the human mind, with which neurologists as well as philosophers and semanticists have been concerned. In this paper only the salient features of the general symbolic process will be reviewed in order to show later how they differ in pathological symbolism.

As Cassirer(7), Langer(13), and others have mentioned, a symbol is something which stands for something else. A most primitive type of symbol is the signal, which is a clue for something else which, however, is implied or present, although not obviously so. For instance, a certain rash is, for the physician, the signal of measles in the child, a certain odor is for the cat the signal that a mouse is around.

A real symbol, however, is something that stands or may stand for something which is absent. For instance, the name John may stand for John when John is absent. Language is a community of symbols. At first a symbol may stand for an external object: for example, the word "mother" stands for the child's mother, in the child's mind, but eventually for every mother. That is, the word will not denote only one object, one mother, but will refer to the whole category of females who beget children. Furthermore the symbol mother is not only communicated to others, but shared with others. That is, all who hear it know the denoting or conceptual meaning of the word "mother."

With the evolution of culture, symbols are created which stand for higher and higher categories. For instance, numbers are symbols which may stand for anything (the symbol 3 may stand for three apples, three books, three men, etc.). Algebraic symbols may stand for every number. Higher symbols are obtained by abstracting parts from lower classes. The new symbol will represent the new class formed by all the members possessing that abstracted part. For

instance, from the symbol "animal" we may abstract the symbol "animal with vertebral column," constituting thus the class of vertebrates. From "vertebrate" we may abstract "mammals" which are those vertebrates which nourish their young with maternal milk, and so on. The members of the higher class acquire some qualities without losing the qualities of the lower class.

The above remarks are insufficient to encompass the complex phenomenon of symbolism but perhaps sufficient to throw some light on the differences between normal and pathological symbolization.

Let us take again as a paradigm the case of Freud's patient, little Hans :

1. The horse as a phobogenic object, at a conscious level is not a symbol, but a signal. In other words, it must be present in order to evoke fear. It is true that the memory of the horse may be frightening to Hans, but this case is already a complication of the situation : the memory is a symbol of the signal "horse."

2. The phobogenic situation is a very concrete situation, and cannot be abstracted from its actuality.

3. The horse as a phobogenic agent is not a symbol which can be shared with others. Hans can communicate his fear to others, but the fear will not be shared by others.

4. Fear of the horse replaces at a conscious level many other fears, which are still present, although not acknowledged. Fear of interpersonal relations may coexist with the fear of the horse, although the patient concentrates on the horse and not on the interpersonal relations.

5. With the development of the illness, a phobia, like the fear of horses, may stand for an increasing number of events and interpersonal situations which evoke fear or anxiety. Larger classes of anxiety or fear-provoking situations or objects can be constructed, but these classes cannot be abstracted from lower ones, as the class of mammals was abstracted from the class of vertebrates. The larger classes do not retain the properties of the smaller classes. Finally we can see that only one element is common to these phobogenic classes : the phobogenic quality. They are thus very arbitrary classes, non-Aristotelian and abnormal classes.

6. This common phobogenic quality, on which the abnormal class is built, at the level of consciousness is not shared by the members of the class. As a matter of fact the patient represses more or less the phobogenic qualities of all the members of the class, except the one which appears in the symptom. In other words, the patient becomes unaware of his anxiety about interpersonal relations, and becomes aware only of the fear of horses. Thus the abnormal class exists only in a state of unconsciousness.

It is important to distinguish these two categories of symbols, which the human mind is capable of conceiving. To confuse them is not only poor semantics ; it means to remain oblivious to the two arrows of human symbolism : the arrow directed toward higher constructs and that directed toward lower constructs. Whereas the normal symbol acquires the property of entities which are not only absent but in some cases even impossible to see or confirm, like the infinite decimal and the imaginary numbers, the pathological symbol (called by me paleosymbol)(1) tends to *reduce to one property* the many characteristics of arbitrary classes. It is not leading to higher constructs and is not interpersonal. Its only constructive use consists in being a pathological defense for the patient, who without this symptom would be even more incapable of coping with more general anxiety-provoking situations.

SUMMARY

Phobias are seen as expression of the general psychopathologic phenomenon of concretization. The fears are concrete representations of more abstract anxiety-provoking situations and relationships.

Phobias have certain characteristics, like dehumanization of the phobogenic object, alteration of the emotional status, retention of active role and of reality test, which can be correlated.

Symbolism in psychopathology presents some characteristics, like concentration on signals and formation of arbitrary classes, which differ from those of normal symbolism.

THE CHAIN OF CHRONICITY¹

ROBERT SOMMER, Ph.D., AND GWYNETH WITNEY, B.Sc.²

Considering its importance in mental hospital psychiatry, there has been very little study of the process of becoming chronic. Most authors who place patients into the categories "newly admitted" and "chronic" make no attempt to show when and how a new patient becomes chronic. The scope of the problem can be seen in the fact that 80% of the patients in public mental hospitals are considered chronic by the criterion of having been hospitalized two years or more(1, 2). Malzburg(5), Brown(1), and Johnson(7) have all emphasized that this two-year mark represents a turning point in the patient's hospital career, for after this his chances for discharge are very slim. A solution to the problem of the chronic patient would be of immense practical value to hospital administrators since each chronic patient is likely to occupy a bed for 20, 30, or even 40 years. It would not be simply a matter of reducing the average length of stay for newly admitted patients from 12 months to 10 months, but rather of eliminating a life sentence given to perhaps one in 20 newly-admitted patients. In England a prisoner handed a life sentence can expect to serve about 8 years. He is far luckier in this respect than a few of the admission ward patients who are transferred to a continued treatment ward.

Chronicity can be viewed as a sequence of connected events, each of which must occur before the patient becomes chronic. This suggests that chronicity can be reduced or eliminated if any link in the chain is broken. In Figure I, the left-hand column represents the chain of chronicity. Some examples should illustrate the way in which occurrence of any one of these right-hand alternatives can keep a patient from becoming chronic. If his peculiar behavior were never noticed by family or friends, then he would not be defined as mentally

ill. However, if other people noticed his peculiar behavior but were willing to tolerate it, he would not be moved to the fourth link, referral to a psychiatric clinic. Even at this point he could still be treated on an outpatient basis. Finally, if all patients admitted to mental hospitals remained on the admission wards and were discharged after a brief time, we would be creating no new chronic hospital patients. The only chronic patients would be the residue from previous cohorts, or, in the words of Morgan and Johnson(7), "the psychiatric failures from previous generations of entering patients."

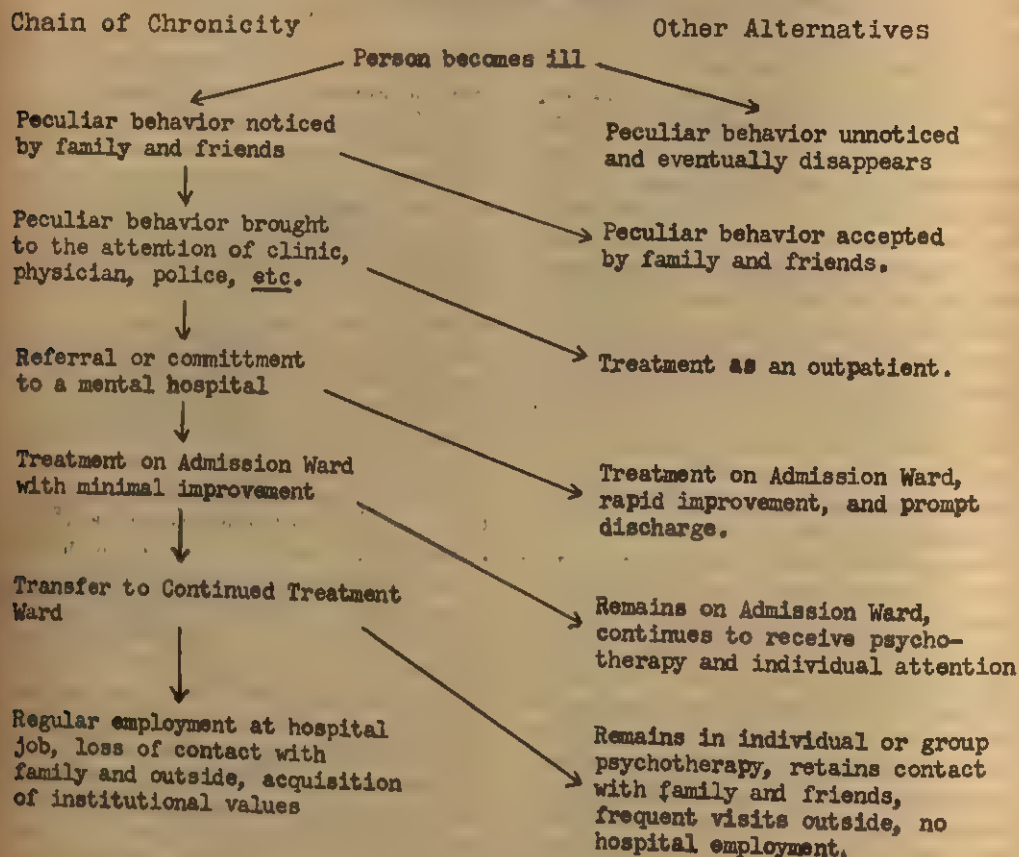

Community psychiatrists have concentrated on the beginning links of the chain, especially the early recognition of mental illness and its prompt treatment on an outpatient basis. The mental hygiene movement has been active in emphasizing such things as the need for guidance counselors in schools and psychiatric training for clergymen. There are also many new and not so new alternatives to committal to a mental hospital, and here can be included the day hospital, night hospital, psychiatric wing in the general hospital, *etc.* All these approaches aim to eliminate chronicity by breaking the beginning links. Psychiatrists and social scientists employed in mental hospitals are working at the other end of the chain. They are coping with such problems as the maintenance of the patient's contact with his family, the preservation of his social values and skills, *etc.* In our own research at this hospital we have found that the longer a patient remains, the fewer visits and letters he receives, the less he is in touch with developments on the outside, and the more his values differ from those of people in the community(8, 9, 10). Passivity, dependence, and a blind acceptance of authority are just a few of the symptoms of prolonged care in what Goffman(3) calls "the total institutions." As mental hospital psychiatrists and administrators have found, it requires a lot of determined effort and research to counteract the effects of this dis-

¹ This research was supported by grants from the Department of Health and Welfare (Ottawa).

FIGURE 1

The Process of Becoming Chronic

culturation. Resocialization aims at getting withdrawn and regressed patients to participate in activities. Reacculturation introduces the patient to the values and attitudes of the world outside; education and vocational training can teach the patient skills that will allow him to compete effectively on the labor market; family and community ties can be re-established by urging families to visit more frequently. These measures all aim to break the end links of the chain, the total institutionalization of the patient.

There has been very little investigation of the fifth link of the chain, transfer from the admission ward to continued treatment ward. Hospital psychiatrists and social scientists have been so busy remotivating and reacculturating chronic patients and applying new therapies to admission ward

patients that transfer from the admission ward to a continued treatment ward has been a relatively neglected process. Perhaps one reason for this is the guilt engendered whenever a patient "fails" his course on the admission ward and must be transferred.

Transfer from the admission ward has more than symbolic significance to staff and patients. Steiner(12), in one of the few studies of inter-ward transfer, found that patients had fairly clear ideas as to which wards were better and worse than other wards, and that when a patient was transferred to a ward that he defined as "better," his hospital adjustment tended to improve, while if he were transferred to a ward that he regarded as "worse" than his previous ward, his hospital adjustment deteriorated. It is also true that staff on the admission ward expect that patients will go

home in a few months, while continued treatment ward staff expect that patients will remain in hospital at least for the next few months. Nurses usually remain on the admission ward longer than patients, while patients on the continued treatment wards usually have longer tenure than the nurses. Furthermore, there are objective and easily observed differences between the admission wards and continued treatment wards. These have been documented in studies at a large number of hospitals, including this one. Compared with admission wards, continued treatment wards have :

1. Lower discharge rate.
2. Less turnover among the patient population.
3. Fewer visits from relatives and friends.
4. Fewer letters both to and from patients.
5. Less contact between patients and psychiatrists or social workers.
6. Emphasis on group rather than individual activities.
7. More patients holding full and part-time hospital jobs.
8. Different kinds of patients. Apart from the geriatric ward, almost all patients on the continued wards are schizophrenic. On the admission ward where there are a large number of alcoholics, manic-depressives, and neurotics, the schizophrenic patients are in a minority.
9. Fewer friendships between patients. This has been shown by numerous studies of friendship patterns at this and other hospitals(14).
10. Less favorable staff-patient ratios and usually poorer physical surroundings. Continued treatment wards usually contain more patients and are more crowded than admission wards, and the patients are more poorly dressed.

All these factors indicate that transfer is much more than a symbolic or administrative act. It not only marks the patient as a "failure," in many cases it insures that he becomes one. Merton(6) terms this kind of situation a "self fulfilling prophecy." This can include rejection of the patient by the staff coupled with guilt at their inability to help him, and loss of hope by the patient accompanied by acceptance of a passive institutional role.

In this paper we shall be concerned with the type of patient who is transferred from admission wards to continued treatment wards, the reasons for transfer listed in the patient's file, the reasons for transfer explained to the patient by the staff, and the patient's interpretation of the transfer.

METHOD

Interviews were held with all those patients who had been transferred to two continued treatment wards during the past two years. These two wards, one male and one female, receive most of the transfers from the admission wards in this 1500-bed mental hospital except for older and physically infirm patients. Excluding those unable to be interviewed, away on leave, *etc.*, 46 patients were interviewed. From the hospital files we found each patient's age, diagnosis, length of stay on the admission ward prior to transfer, number of previous admissions, and reason for transfer. Interviews took place on the patient's ward and concerned his views toward his transfer. Each patient was asked the following questions :

1. Did you know why you were transferred from the admission ward to this ward ?
2. Were you told beforehand that you were going to be transferred ?
3. Who told you ?
4. Were you told the reason for your transfer ?
5. What did this transfer of wards mean to you ?

A few of the patients were unwilling or unable to answer some of the items, so the total number of responses does not always reach 46. Generally speaking, the patients were cooperative and willing to discuss their transfers. However, since in some cases transfer had occurred a year or more before the interview, their opinions were rather hazy. .

RESULTS

Diagnostically, the patients who were transferred were a fairly homogeneous group with more than 85% having a diagnosis of schizophrenia. About half of these were of the simple undifferentiated variety, although there were quite a few paranoids

included. Most of the patients were in their late twenties or early thirties, but this was largely due to the particular wards we studied since all older or physically infirm patients were transferred elsewhere. The preponderance of young adults underlines the seriousness of the problem of the chronic patient. These individuals have life expectancies of 30 or 40 additional years and if they are allowed to become chronic, they can occupy a hospital bed that could serve perhaps 60 short-stay patients.

The next question was how long these patients spent on the admission ward before being transferred. This is essentially an administrative matter and is supposed to depend upon the condition of each individual patient. The first difference is between those patients who return from parole, boarding-out program, or were transferred from other institutions. These patients are all admitted to the admission ward where, in theory at least, they can stay as long as any other patient. Yet, these 8 patients remained on the admission ward an average of only 3 days compared with 54 days for patients who were admitted directly from the community. There is also a slight relationship between length of stay on the admission ward and number of previous admissions. Excluding those who returned from parole or boarding-out, patients with no previous admissions averaged 76 days on the admission ward, patients with one previous admission averaged 55 days, while patients with two or more admissions averaged 44 days.

According to the hospital files, the major reason for transfer to a continued treatment

ward was that the admission ward had proven too disturbing to the patient and that he would benefit from a more stable environment. Other major reasons were that there was nothing more to offer a patient on the admission ward and that he would probably require long hospitalization. Overcrowding on the admission ward was listed as the reason in only one transfer note. In some cases there were specific recommendations for a treatment regime on the continued treatment ward. Four patients were recommended for group therapy, while two patients were recommended as "ward helpers."

The patients had very different interpretations of the reason for transfer. Fully half did not know why they were transferred, and the next largest group believed that the reason was overcrowding on the admission ward. A comparison between the reasons for transfer given in the patient's hospital file with the patient's account of the reason for his transfer is presented in Table I.

Half the patients stated that they had not been informed in advance about transfer, while 8 others said that they were informed only on the day of transfer. This compares with 13 patients who stated that they had been informed about the transfer and 6 who could not remember whether they had been informed or not. The person most likely to have told the patient was the supervisor, while a ward nurse was mentioned next most frequently. Only 4 patients reported being told about the transfer by their doctor. The meaning of the transfer varied from patient to patient. Some appreciated the comparative calm and quiet of

TABLE I
Reason for Transfer According to Patient and Hospital File

REASON FOR TRANSFER	ACCORDING TO:	
	HOSPITAL FILE	PATIENT'S ACCOUNT
Too Stressful on Admission Ward	15	1
Nothing More to Offer on Admission Ward	9	1
Will Probably Require Long Hospitalization	9	2
Previously on Continued Treatment Ward	7	2
Will Benefit from Group Therapy	4	4
Will Benefit from Helping Patients on Continued Treatment Ward	2	1
Overcrowded on Admission Ward	1	10
Requested Transfer	0	2
Miscellaneous	0	5
No Reason Given	7	16

the continued treatment ward, while others missed the activity and stimulation of the admission ward. The majority accepted transfer as another manifestation of the mysterious nature of administrative practice. For example, when asked how he felt about the move, one patient replied, "I didn't really know what to think about the transfer so I did just as the nurses said. I didn't want to start arguing because they seemed to know what's best for a person." Another stated, "I thought it was an order as far as I was concerned. We haven't the right to vote in here, have we? And if we haven't the right to vote, they can't have much concern for our opinions. Maybe some of them got together and decided." Another patient replied, "I don't understand the hospital well enough for it to have much meaning." A patient who preferred the admission ward stated, "I don't like this ward, I wanted to stay on the admission ward because it has better functions. I think they are on a higher scale there. I like the admission ward better because they have the dining room right on the ward and they are not so crowded. This ward is overcrowded." On the other hand, a patient who preferred the continued treatment ward stated, "Transfer means that I have more freedom in going outside. The patients are more incorporated here than on the admission ward." (More incorporated?) "No one bothers nobody." (Do you like this?) "Yes." Others objected to the transfer simply because they preferred to continue in a situation they found comfortable. "I don't like to change, to move around. Stay here—stay there. It's no good to move around. I don't like it. I'd rather stay in one place." Another said, "The transfer didn't mean very much to me. It's almost the same here as over there, but I would rather have stayed over there, I had got used to it."

We also felt that it would be useful to supplement our interviews with an analysis of the social-psychological characteristics of 50 patients who were transferred from the admission ward and 50 patients who were discharged or paroled from the hospital. We followed the hospital career of those patients who were on the admission wards during November, 1959 and noted whether the patient had been transferred to a long-

stay ward or discharged. We then compared the social psychological characteristics of 50 patients who had been discharged with 50 who had been transferred. In both cases the samples constituted the first 50 patients on the list.

From a standpoint of diagnosis, patients who were classified as simple, undifferentiated, or catatonic schizophrenics were more likely to be transferred than paranoid schizophrenics. In fact twice as many simple, undifferentiated or catatonic schizophrenics were transferred as paranoid schizophrenics, while twice as many paranoid schizophrenics were discharged as any other kind of schizophrenic.

It also turned out that, generally speaking, patients who were transferred spent less time on the admission ward than patients who were eventually discharged. There were many exceptions to this of course, but the median length of stay for those patients who were transferred was 64 days while the median length of time on the admission ward by patients who were eventually discharged was 80 days. If a shorter time period is used, the difference is even more intriguing. Within the first 30 days of a patient's stay in hospital, only 4 patients were discharged but 14 were transferred. The differences are not large since there is a tremendous range of time spent on the admission ward but they are sufficient to cast doubt on the idea that a patient is only transferred after all hope of discharge is abandoned. Adherence of this view would maintain that patients are kept on the admission ward as long as possible and only transferred when the prospects for discharge become slight. This view is incorrect since a majority of those patients who were transferred never even remained on the admission ward as long as the median time required for discharge.

In terms of marital status, the data show that a majority of patients who were discharged were married, while the majority of those who were transferred were single. This difference is significant at the .05 level by Chi square Test and supports a similar finding by Morgan and Johnson(7). The data also show that three-quarters of the men in the sample were single, while three-quarters of the women in the sample were

married. This sex difference does not vitiate the preceding difference between transferred and discharged patients, since there was an equal number of men and women in each group.

There was no difference in age between patients who were discharged and those who were transferred. The only suggestive item was that of the 11 patients over 60 in the sample, 9 were transferred and only 2 were discharged.

There was also a trend for the length of time that a patient spent on the admission ward before transfer to vary inversely with his number of previous admissions. That is, the more previous admissions a patient had to a mental hospital, the less time he spent on the admission ward before he was transferred to a long-stay ward. However the trend is much less clear with this sample, although patients with no previous admissions or one previous admission remained on the admission ward twice as long as patients with 4 or more previous admissions.

DISCUSSION

Our previous research into the relationship between length of hospitalization and letter-writing, social attitudes and skills has been more concerned with the effects of chronicity than with its causes. However, it is apparent that spending a specific number of years in a total institution does not automatically produce disculturation since there are such people as Nathan Leopold and the Birdman of Alcatraz who spent more than 30 years behind bars without losing their former social values. There are also the well-documented cases of prisoners-of-war who successfully resisted intensive "brainwashing" campaigns. Persons of this sort who are able to avoid being desocialized or discultured even under extreme conditions do not require much analysis except from the standpoint of individual psychology. It is the vast majority of inmates who are either unable or unwilling to resist succumbing to the prison culture or the mores of the hospital staff who can reap the most benefit from administrative remedies to chronicity.

On a more practical level, many of the transfer notes in the patient's file contained recommendations for specific modes of

treatment. For example, there was a suggestion that one patient become a ward helper, while another should be given a job in the sewing room. It is difficult to say to what extent these recommendations were put into force when the patient arrived on his new ward. We have some evidence from other work that the hospital files are not used very often, especially on the long-stay wards. It seems important that continuity of treatment be maintained throughout the patient's entire hospital career. For the patients in the present study, this was probably more easily achieved on the male continued treatment ward where the patient had the same doctor as he did on the admission ward than on the female continued treatment ward where the patient changed doctors when she changed wards. This, of course, was an administrative matter and a function of the number of psychiatrists available at the time. Yet it does illustrate the need for continuity of treatment, not only upon entering hospital and after discharge but also within the hospital structure.

Even if measures are taken to reduce the number of chronic patients, there will still be chronic *schizophrenics* living in the community. The similarity between the terms is unfortunate since these are really two different problems. A chronic schizophrenic is a mentally ill person whose illness and behavior have reached a stable level, while the chronic patient is a person unable to manage outside of an institution. Many chronic schizophrenics are able to live marginal existences outside of hospital, especially in rural areas or if they have relatives willing to care for them. They may never become hospital *patients*. An especially good example of this was the paranoid schizophrenic described by Trevelyan (13) who lived for 80 years as a hermit. The chronic *patient*, on the other hand, may no longer possess the illness that originally brought him into hospital. His difficulty may be that he lacks the funds or skills to maintain an independent existence (e.g., an indigent older person or a low-grade mental defective) or simply that he has no other place to go. The relevance of the preceding discussion to the problem of the chronic schizophrenic is that he is very likely to

become a chronic patient if he ever enters hospital. We have often observed how older patients, even those admitted for the first time, who are given the diagnosis of chronic schizophrenia are rapidly transferred from the admission ward. Instances of this sort help explain the tremendous differences in the length of time that various patients spend on the admission ward before transfer. One patient in our sample spent 554 days on the admission ward before transfer, compared with 28 days spent by another patient. Although chronically ill persons will still be admitted to mental hospitals and psychiatric clinics, it is important to keep them from becoming chronic patients.

SUMMARY

The goal of the study was to learn something of the process by which a newly-admitted patient becomes chronic. Interviews were held with 46 patients who had been transferred from the admission ward to a long-stay ward. Each patient was asked whether he knew the reasons for transfer, the person who told him, and what the transfer meant to him. The ward files of these patients were also examined to learn the official reason for the patient's transfer. Finally a comparison was made of the social-psychological characteristics of 50 patients who had been discharged from the admission ward and 50 patients who had been transferred to long-stay wards. It was found that most of the patients who were transferred rather than discharged were simple, catatonic, or undifferentiated schizophrenics. Patients who were transferred also tended to be unmarried and on the average

spent less time on the admission ward than patients who were eventually discharged. The implications of these findings for the prevention of chronicity among mental patients were discussed.

ECOLOGICAL FACTORS IN HUMAN MALADAPTATION

JAMES K. FEIBLEMAN¹

I.

The aim of this paper is to discuss the pathological effects of the human ecological situation interpreted as the relation of individuals to cultures. Individual symptoms in social conditioning are to be interpreted as integrative level phenomena. The largest part of the external world, the astronomical domain of the macrocosm, for instance, exists at integrative levels lower than the human. There may be life on other planets, but there are more planets than are inhabited, to say nothing of uninhabitable stars, vast clouds of hydrogen gas. Even on our own planet, while exploration extends within the crust and into the ionosphere, life can be sustained for any length of time and in any numbers only on the surface. But at the human level the non-human areas are represented symbolically and so play a role in *absentia*. We shall consider further what happens to the representation of absent objects.

We begin with the prospect of the external world from the perspective of the human individual. It is a vast panorama of shuffled up materials, statistically more profuse at lower integrative levels. And this is true even for that small segment of the environment which is the available environment or mesocosm. Man lives in the "mesocosm," a middle world between two other worlds which he can explore but in which he cannot live: the world of the very small: the microcosm, and the world of the very large: the macrocosm. Within the mesocosm a bewildering array of stimuli furnish the contents of the continual input to which the individual is subjected. The efficacy of positive responses can only follow the learning of "the insignificance of all irrelevant stimuli" (8).

The environment extends, then, beyond the reach of the individual; but within his reach it contains the ingredients to satisfy tissue needs in varying degrees. We shall not attempt here to deal with all of these (13). His most pressing need, the need for sur-

vival, is met with the proper exercise of the avoidance response, and along with this no doubt go all varieties of aversion: fear, aggression, and flight. But with the needs for feeding and breeding, tension arises. Conventional types of thanatophobia are obscured by the more pressing search for food and mate, which are, respectively, less common than the ground he must have under his feet and the air he must breathe into his lungs. Muscle tonus and the oxygen supply take care of themselves; but hunger and sex cravings require more concentration. The constant foraging and courting constitute pressures, and when children are the outcome of the latter, it only increases the pressure of the former.

Thus the individual is driven back to the consideration of how these needs can be anticipated and perhaps met with a long-term supply. To escape the tyranny of the immediate environment, it is necessary to discover how to anticipate future tissue needs and to store up satisfactions to meet them. Communication with others having the same problems becomes urgent, for the successful outcome of such discovery requires the execution of tasks which do not lie within the range of the powers of the individual: hunting large animals, planting, protecting and harvesting vast crops. The entire enterprise, planned for the future, is a way of dealing with absent objects (7) in the general terms of a colloquial language. Inevitably, the relationship between these need-satisfactions is discerned, and curiosity aroused. The individual takes off in search of facts and causes.

It is important to notice, however, that a drastic reversal has taken place, one so subtle as to go almost unnoticed and yet so far-reaching as to constitute another stage in biological evolution. The proposition that *All inquiries are conducted for the sake of maintaining existence*, has been converted to the proposition that *All existence is maintained for the sake of conducting inquiries*.

Let us consider some of the consequences of the conversion. In the first place, we are

¹ New Orleans, La.

of course talking about living propositions, propositions as exemplified in practice, not about the natural history of human thoughts. Men once went where their curiosity led them for the purpose of survival; now they endeavor to survive in order to go where their curiosity leads them. The turn has been called not by the recognition of it in discourse but by the events themselves.

In the second place, such a reversal plays havoc with the drives toward the satisfaction of such tissue needs. The brain once occupied a subordinate role, being subservient to stomach and gonads. Now stomach and gonads function in order that there shall be a continuity of activity for the brain. But there is a further dislocation; for bits of the environment are internalized by the stomach and gonads, but the larger environment is contacted by the brain.

Evolutionary development is inverse to morphological dependence(4). The higher centers, such as the frontal lobes, were late arrivals on the phylogenetic scene; but on the other hand, the brain depends upon the other organs for its survival, and within the brain the higher centers depend upon the lower. For instance, circulation throughout the brain depends upon the proper blood pressure; and a continual fall in the blood sugar would produce at first loss of consciousness (with involvement of the frontal lobes), next convulsions (the cerebellum) and finally respiration difficulties (the medulla) and death.

Finally, due to the external nature of the aim of inquiry, material objects are altered in the course of it. Inquiry involves analysis, but it also leads to synthesis: social groups are formed and their organization established, tools are designed and techniques devised, and both are copied, and structures are erected and inherited. The accumulation achievement replaces the continuity of conditions. In place of the mere repetition of behavior by the successive generations, there is a construction of culture.

As for the individual, the knowledge of what exists now becomes the object of his search. He has turned into the creature who survives in order to inquire, erecting quasi-permanent answers into institutions, social relations operating, so to speak, in a neurological setting. For now the depend-

ence of his organism upon the environment can be analyzed into one of dependence of the balance between homeostasis and the brain stem reticular activity. He bears the scars of his experience as collections of engrams, organized into explanatory beliefs: retention schemata both private and public. Thus equipped, he supplements the neurological homeostasis with a cultural homeostasis extended to include material objects (3). Such objects usually have the character of artifacts, because altered through human agency. His encounter with the environment in search of tissue-need satisfactions has resulted in an equilibrium between the retention schemata and the civilized external world. The continual interchange has been widely recognized; for it is acknowledged that "the cerebral instrument breaks down with zero input"(14) but on the other hand breaks down also when it is no longer able to sustain contradictions without diremption. It is the latter variety we have largely to deal with in psychopathology. Being human means sustaining private conflicts, and being social means sustaining public conflicts (as within and between the retention schemata). The neurotic is threatened by diremption and the psychotic has succumbed to it.

III.

Technological cultures, as products of the attempt to solve the long-term supply problem necessary for survival, themselves raise survival problems by bringing into play stresses of a peculiar type. In simpler cultures, in our own culture, too, in fact as late as the early 19th century, the individual was constantly subjected to external stresses and internal strains. Inter-personal relations, customs, institutions, with their conflicts and struggles, always exist. But the external stresses were limited to social struggles and the internal to the usual fear of death. In the complex cultures brought about more lately by the combination of the applications of science and industrial technology, a cultural homeostasis becomes more difficult to achieve and maintain. There are, of course, many psychoses to which youth is susceptible, such as hebephrenic schizophrenia and the psychopathic personality. But the aged are more susceptible, and in

1960 in the United States it was true that "one out of every three beds in public mental hospitals is occupied by a person 65 or older" (9). Rapid social change erodes the ground on which such a homeostasis could rest.

But there are worse difficulties. The chief feature of the scientifico-industrial culture which technology has developed is its abstractness. Forays into the microcosm and macrocosm have been successful. Men have returned with their scientific spoils, and the result is to change the character of the mesocosm, which now contains artifactual inhabitants seldom understood by non-specialists, with their effects which are less understood still. The average individual lives for the first time in a world populated with material objects and procedures he does not understand and is perhaps incapable of grasping. He drives a car but does not fully understand the principle of the internal combustion engine; he operates a television set but does not comprehend the principle of the vacuum tube; he engages in business but does not understand the modern complexities of banking; he ingests vitamin capsules or antibiotics without the slightest glimmer of how they were constructed or of what they do. He is both benefactor and recipient of inquiries predicated on the search for a solution to the long-term supply of basic tissue-needs conducted at the level of the inexhaustible tissue-need of inquiry, and yet he remains in ignorance. And at this level he is expected to adjust. The scientifico-industrial culture like all other cultures, resulted from human behavior; but now the capital city, which is one result, itself provides the new conditions to which it becomes necessary for men once again to adapt. This time they have provided themselves with the stimuli as well as the responses. They have invented their own environment.

Only, as it turns out, they have done so without anticipating and estimating the prospects and costs of adjustment. The mesocosm is for the first time a world of their own devising yet it now develops that they did not figure it closely enough. The immediate environment is an altogether artificial environment. They have made themselves a world in which to live, without con-

sidering just what it would mean to live in it. If it is true that the dependence of the organism upon its environment extends all the way from simple cell-division and the acid-alkalinity balance to the contents of excretions and the metabolic interchange, then what adjustments in body structure will be required for survival in the new social world? To live in the mesocosm now means to have all the stimulation of the receptors coming from the cultural environment. The ears are assailed by man-made sounds, from street noises to jazz. Few are able to escape from the roar of the traffic of some city. The eyes are continually in contact with artifacts. What with the skyscrapers, the obscuring city lights by night and the smog by day, the sky is hardly ever visible, and there is no incentive to view it. The nose is assailed by odors artificially produced, from the smell of asphalt and inhabited interiors to that of perfumes. Everything except artifacts is out of reach so that the sense of touch is equally confined. There are few foods ingested that have not been altered by the process of manufacture in some way, and thus even taste is artificially conditioned. Finally, even the muscle sense is stimulated by the activity of the muscles in exertion against artifacts, moving them about or altering their shape.

All of this is bound to have serious biological repercussions. Anatomical development over its long history has been shown to be a matter of adaptation through natural selection. It is assumed that this process accounts, for instance, for the adjustment of the respiratory system to the contents of the atmosphere, of the muscular system to the geosphere, of the digestive system to the biosphere, and of the nervous system to human society (the "siosphere").

Now in maladaptive behavior, there is usually phyletic extinction; but it is a peculiar feature of human society that it endeavors to bring the victims along. This has the double merit of helping them and of learning from the causes of their predicament how healthier specimens may better adapt and so survive. Space medicine is a recent development intended to study how to provide for extraordinary conditions, stresses, for instance, brought about by

gravity increases and by enormous accelerations in speed. But what is not equally recognized is that there are, so to speak, no ordinary conditions. The life expectancy has been extended and the buffeting multiplied.

Look at the individual from the point of view of the cultural environment in which he is presently immersed. See him as the recipient of stimuli projected from artifacts. He shaves with an electric razor, rides in a subway, rises in an elevator, operates a typewriter or a high speed computer, while his wife does the washing in a machine designed for the purpose, cooks on an electric grille and waits for his return to relax with the radio. They live in a world populated by little motors which they do not understand and which far outnumber them. But this is an empirical area and there is an experimental science which investigates it. The domain is that of social psychology, which is the study not of social groups and their behavior but of the modification of individuals by institutions and cultures.

The common world is a physical, chemical and biological world. The social world is a selection made by the alternation of responses to environmental stimuli in the form of constructions: tools, symbolic communication systems, institutions, cultures. Here the group decides, though not as a group, but rather as individuals in whom the group participates(2).

The gap between cultural artifact and psychological individual is the one the neurological circuit has to bridge. The issue always turns on whether the diversity of organic reactions can be stretched to cope with the complexity of conditions produced by the scientifico-industrial culture. One method is to extend technological assistance to the various organs: spectacles for the eyes, magnifying devices for the ears, prosthetic devices for the limbs, and so on. We see the problem more clearly in the case of a man who operates his television set with an artificial hand, watches it through corrective glasses, and listens to it by means of a hearing aid. These mechanical extensions to the receptors and effectors are in many ways quite satisfactory; and although they contribute toward enlisting the individual in the culture in a way calculated to render him an irreversible dependent,

they also help to stave off the reactions in which the breakdown of functions would otherwise occur.

We may, however, do well to consider a set of reactions in which breakdown does occur. A formidable one concerns language. An early and well marked mental defect is the loss of the ability to deal with abstractions. This may take one of two forms: either the individual loses the ability to abstract, or he loses the ability to control certain of his abstractions.

Inability to abstract is a well known maturational defect, but sensory and motor disturbances are often accompanied by symbolic deficiencies. Patients with brain injuries in the general region of Broca's area, the third left frontal convolution, avoid abstractions in favor of concrete terms; they cannot understand classes and class relationships. Aphasia is manifested by (among other symptoms) a lowered capacity for abstract thought, a deficiency shared by psychopathic personalities.

If the loss of the ability to abstract characterizes one type of mental disease, the loss of the ability to control abstractions characterizes another. There are at least two varieties, exemplified by the hebephrenic and the paranoid schizophrenics. In the former case, we have the spectacle of displacement into a fantastic private language from the failure to participate in conventionally established abstractions. In the latter case, the phenomenon is one of uncontrolled conventional generalization. The avoidance posture of the paranoid compels him to select particular threats in his environment, or to mistake neutral or friendly elements for threats. As the response of rage is made to the stimulus of fear, the inductions of the paranoid proliferate indiscriminately. "This man is against me" implies 'All men are against me' implies 'I am being persecuted.' The organization of the antipathy of all men is unwarrantedly assumed in this enthymeme.

Neurotic behavior is maladaptive behavior; psychotic behavior marks the retention of maladaptive habits, their establishment as a personal but less than provisional security. The motivation of survival has replaced the need of inquiry, a distinct regression. At the same time, an autistic ad-

justment is not an acceptable settlement, for it decreases the external stresses at the cost of increasing the internal strains. Hence the prevalence of suicidally inclined patients in mental hospitals.

There is, as Walter has pointed out, only one chaos(15). The chaotic world of the psychotic is to that extent a common world. But there are many types of order. The approximation to the condition of chaos on the part of the stimulus-world is an approach to zero input. The world of the hebephrenic is a chaotic world from which stimuli have been held to a minimum, and as a consequence the activity of the higher centers of his nervous system no longer constitutes a learning process. External order, in short, is a condition of proper functioning for the organism, and external order can be apprehended only through the abstract symbols of a technique of communication, which is to say, through a language.

The history of the organism, which must be taken into account in explaining its behavior, does not mean references to the past but to those alterations in the organism made in the past but existing in the present, alterations such as the posited engrams and the more manifest habitual behavior patterns. Unfortunately for the stressed individual, these include conflicting schemata: the public retention schema containing the ideals of social behavior, as taught in early years by parents, teachers and textbooks, and the statements of public officials; and the private retention schema containing the hard facts as personal experience has revealed them: as for instance the cutting edge of the selfishness or the dishonesty of others, bitter disappointments, secret but forbidden enjoyments, short turns to success. In other words, as the two types of schemata collide, the conditions for private conflict are laid down early and well. They insure that the individual will have the task of integrating his own conflicting schemata before adapting to the alien world of his culture's devising. If he fails to succeed in this, he has little choice but to subside to lower integrative levels; lower organisms are not capable of sustaining diverse retention schemata, and psychotics no longer undertake to do so.

The exceptions, perhaps, are sufferers

from paranoia, who keep the external world separate from their delusional systems, and the psychopathic personalities who persist in expecting agreement from the external world for theirs. The high order of logical structure retained in paranoia for the delusional system is spread by the psychopathic personality thinly over the connections between his own goal-seeking and the objective facts. Both are victims of atrophy of the feelings, and lack all empathetic reactions. Something of this sort is suggested by the discovery of the dysfunction of the autonomic system in psychotic individuals(10) but the difficulty is in all likelihood more widespread.

Psychotics are quite capable of dealing with artifacts, but the social contacts have been cut at the level of inter-personal relations. What does this mean, except that the psychotic denies an interaction and looks for affects that flow in one direction only. He can take, but he is in no position to give.

III.

In the first part of this paper were set forth some of the stages in the process whereby cultures have developed out of the attempts to anticipate and prepare for the satisfaction of future basic tissue needs. We saw how the brain, which came to the fore in this effort to help feeding and breeding, ended by taking precedence over them; so that whereas it had existed for them they now had come to exist for it. This new adjustment led to a species of human maladaptation. In the second part of the paper it was shown how, in the attempt to live in the environment brought about by the cultures they have produced, men have tended to break down. Psychoneuroses and psychoses are the results of the stresses of complex scientifico-industrial cultures.

Now it will be necessary to address ourselves to the solution of problems raised by the existence of culture as the human environment. Cultures are not new and the individual strains of living in them are not new, either. But in earlier cultures, the cultural environment was a small part of the available environment. In the scientifico-industrial cultures it begins to encroach strongly. Thus it raises problems which, if not altogether novel, present difficulties to

a degree that amounts to a major crisis. What, if anything, can be done about it?

We may perhaps begin the discussion of this question by taking a page from the science of neurology. There we find two conflicting conditions. It seems that for the normal functioning of the human organism both the constancy of the external environment and differences in stimulation are required. Perception appears to hang upon the former and consciousness upon the latter.

Perception is of a physical world independent of the observer, a world which is stable, rigid, solid and orderly in a way which, as Gibson says, gives "objectivity to our experience" and makes perception itself possible(6). For perception—in this case visual perception—is constructed to encounter such conditions and relies upon finding them. Gellhorn goes so far as to assert that "the constancy of the external environment is a cortical function"(5), without which the individual would neither be suitably oriented nor able to act purposively.

That consciousness would not be possible without differences in the objective field of consciousness has been shown by experiment(1). Monotonously repeated stimuli lead to sleep. The inner ear, which is so sensitive to any irregular forces, does not react at all to uniform motion. Order among stimuli is relaxing. Hypnotism relies heavily upon this effect, and anyone who has driven a car for hours over a straight and level road can testify to its truth. The uniformity of perfect order or of chaos allows for no stimuli at all, and without the continuous input of diverse stimuli there is no consciousness.

How, then, is this paradox to be related to the problem of resolving the psychopathological strains which complex cultures impose upon their individual members? The next step is to discover the optimal pragmatic set of conditions under which cultures can be maintained with their immense benefits, but without serious damage to the individual. How much progress in cultures can the individual support? There are, once again, two parts to this question. There is the problem of the internal dislocation in the individual: the distortion of the private retention schema by the public.

And there is the problem of the external dislocation of the culture: the distortion of the institutional structure by the ascendancy of a particular institution.

Both problems resolve themselves into one again when we consider that the state of the culture is operant in both cases with equal effectiveness. For the internal dislocation of the individual depends upon the character of the cultural stimuli to which he is subjected, and the institutional state of the culture depends upon his own sense of what institutions are most important in conducting inquiries. Thus at the present time science is the crucial institution; it offers not only to feed the basic tissue need of pure inquiry but also to further the long term supply of satisfactions for the survival needs. As a consequence the rapid rate of change in fundamental theory brought about by the new conceptions of matter and of the cosmos has compelled a revision of the public retention schema, while technological advances have improved the food supply, both as to quantity and quality, increased the safety of birth-control and provided efficient contraceptives.

However, these changes have been brought about at a rapid rate, and the resultant challenge to the homeostasis of the individual is alarming. Too much and too frequent stimulation has its price. It is possible to over-stimulate, with a result not unlike the absence of all stimulation. To quote an athletic director, "these ailments are continuous—always something new" (11). The life expectancy has been dramatically extended but so has the prevalence of mental illness. The enormous rise in the population of our mental hospitals in recent years, together with the immense number of psychoneurotics and even psychotics who are able to maintain themselves on a precarious balance outside, is well known.

At this point, it seems impossible to turn the clock back. The cerebral development, and in particular the development of the frontal lobes, prohibits the mere existence of man at the monotonous level at which change and progress in living conditions prevails. The cerebrum assures the continuance of inquiry whereas the more fundamental mechanisms of the reticular forma-

tion of the brain stem requires a constancy of the external environment. From the stimulus end, the cultures we inherit make more complex inquiry possible but also block them out by vested interests in already existing knowledge. Science is inquiry incarnate, but government has now joined religion in regulating such inquiry and by consequence slowing it down or giving it more practical direction.

Thus the psychological solution could be effected by a cultural shift: easier adjustment of the organism to a slower gain in the increase of knowledge. As for the mentally unfit, this would be especially true. If stronger measures are needed, then deliberate cultural regression could be practiced. Hospitals for mental diseases ought to be constructed in the remote countryside, and approximate as near as possible to primitive conditions. Outdoor plumbing, wood fires for heating and cooking, crude accommodations, all designed to allow the readjustments to be slower. This is a possible solution of the future, but it is not the ideal one. The ideal solution would combine the peace and serenity of conservatism with the excitement and vitality of progress, avoiding both the stalemate of repetition and the turmoil and insecurity of rapid change. There would be no longer any traditional ways of doing things but instead habits would be hooked up to an irregular rate of advance. Another biological adjustment would come into play: the tuneable homeostat of a servomechanism as the functioning model of the central nervous system (12).

So much for the psychological subject. As for the object, it would have to involve a better adjustment between institutions. No single institution would be allowed to run away with the others, but novelty would be provided by all. Cultural lags in institutional advancement would be studiously avoided and the proper institutional relations discovered and established. The emi-

nation of human maladaptation depends upon the provision for a proper cultural environment, the ecological ideal upon the proper interdependence between the organism of the individual and the environment of the culture.

THE MEASUREMENT OF AN INHIBITORY PROCESS IN HUMAN HIGHER NERVOUS ACTIVITY: ITS RELATION TO ALLUSIVE THINKING AND FATIGUE¹

N. McCONAGHY, M.B., D.P.M.²

THE NATURE OF ALLUSIVE THINKING

Bleuler(1) was the first psychiatrist to point out that schizophrenics who have recovered from their illness in all other respects continue to show, in milder form, the disordered thinking they suffered from when frankly ill. This observation was repeated by Skottowe(2) who stressed, in addition, that in the recovered patient it is only abstract thinking which remains affected. Concrete thinking, the ability to relate his day to day experience may be disturbed in the schizophrenic; the recovered patient only shows evidence of thought disturbance when he abstracts, or makes deductions, from his experience.

This observation of Bleuler and Skottowe has not been generally confirmed by the majority of psychiatrists. This is considered by the author to be due not to the inadequacy of the descriptions of Bleuler and Skottowe but to the fact that, as with other clinical phenomena, training is required for its detection. If, when learning to recognise the various type of heart sounds, one had to rely solely on the descriptions in text-books without being able to check one's observations against those of the trained physician, the possibility of mastering this task with accuracy would be considerably reduced. In fact, even with the intense training in the detection of physical signs given in most medical courses, recent studies(3) have shown that the reliability of senior physicians to detect such signs as impaired breath sounds, hyperresonance, impaired cardiac and liver dullness is much lower than would be expected. However, no one would argue from this evidence that these conditions did not exist. If this applies to the detection of physical signs it must apply even more so to the detection of differences in the mental

states of individuals. For there to be reasonably common agreement as to what are meant by such terms as "flatness" or "incongruity" of affect, there must be repeated demonstrations of these conditions by the teacher to the student. Still more so must this consideration apply to the recognition of a type of abstract thinking so subtly different from that present in the rest of the population that its existence has been so far noticed by only two psychiatrists.

For this reason, the author, in putting forward yet another description of this type of thinking, does not expect that it will enable people to recognise this condition clinically. However, as he considers that the present study establishes its existence and throws light on its causation, it is desirable that the reader has as clear an idea as possible of its nature. Both Bleuler and Skottowe observed this thinking only in recovered schizophrenics and so regarded it as a residual symptom of this illness. However, it has already been advanced by the author(4) that this is the normal form of abstract thinking of a percentage of the population. That is, the majority of persons in whom this thinking is found have never suffered from schizophrenia. It is considered that this mode of thinking acts as, or indicates the presence of, an inherited predisposition to this illness, thus explaining its presence in those who recover from this condition. It has been shown(5) that it is present in one parent when it is present in a patient and the present study gives further evidence of its occurrence in normal individuals. Furthermore, it is considered that it conveys certain advantages to the possessor(4). Therefore, to avoid any implication of pathology and to stress one of its important positive aspects it will henceforth be referred to as "allusive thinking."

Though the author is convinced that this type of thinking is either present or absent in any one person, it is not suggested that when present it does not vary in degree. In

¹ Read (in part) at the annual meeting of the Australian Association of Psychiatrists, Adelaide, South Australia, Oct. 17-20, 1960.

fact, as Bleuler noted, with some individuals one only becomes aware of its presence after persistent observation. One reason for this is that as only abstract thinking is affected, unless the subject being examined can be made to think at this level, one cannot be sure that the potential for this type of thinking is absent.

As it is necessary to make the subject abstract, it is easier to detect the more obvious forms of allusive thinking in an interview situation, where the nature of the conversation can be determined by the examiner. Also, this allows the possibility of questioning the subject as to what he meant, since the examiner must be convinced that the subject is completely satisfied with his statements and that any obscurities in them are not due to his clumsiness of speech or an inability to express himself of which he is aware. In an interview, allusive thinking manifests itself in two ways. Firstly, words are used which are slightly inappropriate because the subject expresses himself in too few words (over-condensation) and at a more abstract level than is suitable, as in the following example:

Examiner: How are you now compared to how you were 5 years ago?

Subject: The only difference now is loss of material benefits.

Questioned as to what he meant by this he said he had been forced to sell his house and car to pay for analytic treatment. Secondly, ideas are expressed imprecisely, again, generally, the fault being in the choice of over-abstract concepts. The following examples are all taken from interviews with the students of the experimental group: "The ultimate questions of motivation are non-psychological." Asked what this meant he replied: "It (psychology) may tell you the cause, it won't tell you the reason people do things."

Another spoke of *The Cocktail Party* which had been very meaningful to him. Asked what meanings he saw in it, he said of the people in the play, "The ritual gave them a sense of conformity which gave them a sense of continuity."

These examples demonstrate that practically complete failure to communicate can result from allusive thinking.

It is not, however, claimed that persons

with this mode of thinking always fail to convey their meaning, but only that they use words inappropriately in a characteristic way. Often the meaning is apparent and just as many psychiatrists learn to communicate with schizophrenic patients so well they lose the ability to appreciate the existence of schizophrenic thought disorder when it is often grossly apparent to newcomers in psychiatry, so this lesser form of unusual thinking passes unnoticed by most people for the same reason. Of course, one does not rely on the occurrence of one such expression in a person's speech to diagnose this condition, but on their repeated employment.

When this sort of analysis is made of speech the objection is usually put forward that various psychological factors would account for these statements. Of course this is so. Perhaps the most probable would be that these persons lack verbal fluency. To demonstrate that this need not be the case the following example is taken from *Voss*, widely considered one of the greatest of the post-war novels.

How her defection (from religion) had come about was problematic, unless it was by *some obscure action of antennae*, for she spoke to nobody who was not ignorant, and innocent, and kind. Yet, here she was become what, she suspected, might be called a rationalist. If she had been less proud, she might have been more afraid. Certainly she had not slept for several nights before accepting that decision which had been in the making, she realized, several years. Already as a little girl she had been *softly* sceptical, perhaps out of boredom; she was suffocated by the fuzz of faith. She did believe, however, most palpably, in wood, with the reflections in it, and in clear daylight, and in water. She would work frantically at some mathematical problem, even now, just for the excitement of it, to solve and know. She had read a great deal out of such books as had come her way in that remote colony, until her mind seemed to be complete. There was in consequence no necessity to duplicate her own image, unless in glass, as now, in the blurry mirror of the big darkish room.

Apart from the somewhat odd expressions, there is a degree of irrelevance in many of the associations and there is at least a degree of failure to communicate the

meaning of the last sentence, in that one cannot be entirely sure of its meaning. If "duplicate her own image" means believe she has a soul, this utilisation of both the abstract and concrete meanings of the phrase is an excellent example of the author's mastery of allusive, evocative writing.

It was previously stated that in fact the allusiveness of such thinking was one of its greatest advantages. By this is meant the ability to allude to more than one concept, without their being actually stated. One's clinical impression is that the quality of attention is different in persons with this thinking. It is coarser, that is, it includes more concepts, but cannot become narrower, so that the concepts that are included in attention at any time are not accurately defined. Hence those with this thinking can convey more, but in an imprecise way. Here is an example from the novelist Ronald Firbank. He writes of one of his characters, Lady Parvula de Panzoust, who could perhaps be best described as a deliciously wicked woman. "She was looking charmingly *matinal* in a simple *invocative* (this he has himself emphasised) hat . . ." The religious overtones of both these words add enormous subtlety in their context as his art lies in the evocation of a world at once religious, depraved and artificial.

The author of course realises that he has not disposed of the many alternative elaborate psychological explanations that could be put forward to account for the employment of the types of associations described. He prefers to call upon the principle of economy, though aware that unlike other scientists, psychiatrists tend to prefer its converse, the principle of affluence—never employ a simple explanation if a more complex one will serve your purpose. He therefore argues that if it can be demonstrated that the behaviour of persons assessed as showing allusive thinking differs in predictable ways in a variety of situations from that of persons without such thinking, the existence of this type of thinking as a clinical entity is sufficiently established. It has been demonstrated elsewhere(6) that the performance of allusive thinkers on a Sorting Test differs in this way. The present study

investigates their behaviour in a learning situation.

THE PRESENT STUDY

It has been suggested(4) that allusive thinking is due to a weakness of an inhibitory process in the higher nervous activity of the person demonstrating the condition. This study is designed to test this hypothesis. Such an hypothesis is only comprehensible within the framework of a theory which explains mental activity in terms of the interaction of excitatory and inhibitory connections. Both Bleuler and Pavlov have independently put forward such a theory. Neuropsychological evidence for the theory has recently been advanced by Kaada, *et al.*(7, 8), who have suggested that this generalised inhibition accompanying mental activity is produced by the arousal response. Bleuler(1) considered that the condition he called schizophrenic thought disorder—the employment of inappropriate associations—was due to a weakness of the inhibition which accompanies attention and produces the "constriction of the field of conscious awareness" characteristic of all normal thinking. Pavlov(9) found that certain dogs showed an inherited weakness of inhibition which resulted in their showing certain characteristic "personality" traits. The author (4) combined these two theories and put forward the hypothesis that allusive thinking in humans is due to a similar inheritance of a weak inhibitory process.

If this hypothesis is correct it must mean that there are mechanisms common to the nervous systems of both man and dog and it is such a mechanism which is affected in this way. Therefore, to test this theory it would be most reasonable to investigate behaviour which is influenced by the action of such a common mechanism. The learning of a serial set of responses is the best known example of such behaviour. Munn(10), comparing the performance of humans and rats in learning a maze states:

The number of trials required to learn, the number of errors made, and the time consumed, are not greatly different between rats and college students. Sometimes the rats come out slightly ahead and sometimes the students.

The mammalian nervous system has through its development been enabled to master tasks of greater and greater complexity. However, its ability to master this simple task—the learning of a serial set of responses—has not significantly altered. Here it would seem its performance is limited by some characteristic, unalterable by evolution. Such a task then is most likely to provide information about a mechanism common to the mammalian nervous system irrespective of species.

When the learning of a serial set of responses is investigated it is found that the middle portion of such a series is the hardest to learn. Within the framework of Pavlovian theory this can only be due to the operation of an inhibitory process and it has been so regarded by workers utilising this framework as well as by other learning theorists who also accept a concept of inhibition (11-13). The author has in the present study investigated the hypothesis that this inhibitory process is weaker in persons who show allusive thinking, that is, that those with allusive thinking will show less difficulty in learning the central portion of a serial learning task than will persons without this type of thinking.

THE EXPERIMENTAL GROUPS

The results obtained with two groups are reported, as the subjects of Group 1 were not available to repeat the experiment with an alternative design.

Group 1 consisted of male undergraduates of the University of Adelaide, males only being employed as they were also investigated with a conditioning technique devised by Lovibond which was suitable for use only with this sex. (The results obtained with this technique are being reported separately). Fifty-five students, mainly the male students taking psychology, were interviewed individually for approximately 10 minutes by the author, who attempted to divide them into those with and those without allusive thinking on the basis of the description given above. It would, of course, be expected that the reliability of this assessment would be lower than that which would be obtained with longer and repeated interviews. However, it was considered possible to classify in this way 52 of the

students. Of these, 38 came for investigation at the subsequent session and so made up Group 1. Of these 38, 18 had been classified as having allusive thinking; 20 had not. The mean age of the former was 22.9 years (range 17-34) and of the latter 21.9 years (range 18-39).

Group 2 consisted of 20 adults well known to the author and selected by him to include 10 persons with and 10 without allusive thinking. All with the exception of a housewife and a fifth-year male medical student, were working effectively at a professional or executive level and all were free from signs of overt psychiatric illness. Apart from the student all were university graduates or of equivalent educational status. The sub-group with allusive thinking consisted of 7 males and 3 females with a mean age of 31.2 years (range 23-38) and that without it also of 7 males and 3 females, with a mean age of 31.0 years (range 24-35).

METHOD

It was found by Pavlov (5) that the nervous "type" of dogs could be assessed more easily if they were tested after their nervous processes had been strained by carrying out a difficult task. This finding was utilised in the design of this experiment. Subjects were required to learn two lists of low association nonsense syllables (this being found a difficult task by most people), followed by two lists of words. This design was used with Group 1. The subjects of Group 2 were given two stylus mazes to learn between the nonsense syllables and the words. As maze learning is accomplished by most people with little concentration, it was considered this would allow the nervous processes to partially recover and thus might make differences in nervous "type" more obvious. The subjects of Group 2 then repeated the experiment, learning first a list of words, then lists of nonsense syllables and then more lists of words. This design was introduced to demonstrate that learning lists of nonsense syllables did in fact strain the nervous processes. The details of these 3 designs are given in Table 1. One minute intervals were allowed between the learning of each task. The lists of words and nonsense syllables were presented by means of a memory drum which exposed one word

+ N. Sylls. = Nonsense Syllables.

or syllable for a period of 3 seconds and then instantaneously replaced it with the next. Learning was by the method of anticipation. In each case the lists of nonsense syllables contained 9 items and the words 16. The stylus mazes contained 16 choice points.

In the case of each task, learning was carried on to two consecutive correct performances of the list or maze, or to 16 trials, whichever came first. The nonsense syllables were chosen from the lists of those of low association value given by Hilgard (14). In the case of Group 1 and Group 2 Experiment 1, the words were chosen to make up two lists, one of words having low association value with each other, and the other of words having high association value with each other. (This difference is not significant for the results being reported; other results are being published separately.) The words for these two lists were derived from data of Mednick and de Vito (15). In the case of Group 2 Experiment 2 the words were simple words chosen at random from the dictionary.

RESULTS

The difficulty each subject had in learning the central portion of the lists was quantified by the use of the following formula, the resultant being termed the Inhibitory Index:

Total number of items
learned correctly up to but
exclusive of the first correct
performance or in 16 trials,
whichever criterion was
reached first.

Inhibitory Index =
(I.I.) $\frac{\text{Total numbers of items in
the middle } \frac{1}{2} \text{ of the list
learned correctly in the
same number of trials.}}{\text{Total number of items
learned correctly up to but
exclusive of the first correct
performance or in 16 trials,
whichever criterion was
reached first.}}$

If no inhibition were operating there should be equal likelihood that items within or without the middle $\frac{1}{2}$ would be learned and the I.I. would = 4. The stronger the inhibitory process the more the I.I. would exceed 4.

The method of assessment used was based on the hypothesis that learning the nonsense syllables would weaken the inhibitory process being measured. It is considered that this is a labile, dynamic process, changing in intensity with the condition of the nervous system, as Pavlov (5) found with the inhibitory process in dogs. Hence it was decided to attempt to sample the range of the fluctuation of this process by obtaining more than 1 measurement. For this reason, 2 lists of words were used in each experiment, considerations of time preventing more than 2 being used. In the experiment with Group 1 and with Group 2, Experiment 2, the word lists were administered immediately after the nonsense syllables so the inhibitory process was being measured at its weakest. Hence in these 2 experiments it was decided to compare the lower of the 2 values of the I.I. for each subject. With Group 2, Experiment 1, the maze learning was interposed between the learning of the nonsense syllables and words to allow the inhibitory process to commence to recover. Hence the inhibitory process was being measured in its recovery stage and it was decided to compare the higher of the 2 values. The decision to employ these methods of assessment was made at the commencement of the experiments.

In all 3 experiments the trend was in the predicted direction, that is, persons with allusive thinking had lower I. Indices than people without. In the case of Group 2, the scores of 14 of the 20 subjects, (70%) were

TABLE 2

in the direction predicted. This trend did not reach significance. In the case of Group 1 the scores of 25 of the 38 subjects, (66%) were in this direction and with this larger group this difference is significant at the 5% level, using the Mann-Whitney test. The I. Indices for this group are given in Table 2.

To investigate the hypothesis on which the method of assessment was based, that the learning of nonsense syllables would weaken the inhibitory process under investigation, Experiment 2 with Group 2 was carried out. The I. Indices for the subjects' performance on word list¹, administered before the nonsense syllable learning, were compared with the average of the two I. Indices for the performance on word list² and word list³, administered after the nonsense syllables. The I. Indices after nonsense syllable learning were lower than those before. This difference is significant at the 5% level, using the Wilcoxin test of paired replicates. These scores are also

given in Table 2. As the subjects learned list² and list³ better than list¹, presumably an effect of practice, it could be argued that the difference in the I. Indices is due to the greater number of words learned in 16 trials. To allow for this the I.I. was recalculated for each subject's performance on list² and list³ up to the trial when they had learned the number of words nearest to that learned on list¹. The average of these two I. Indices was still lower than the I. Indices for the subjects' performance on list¹. This difference is significant at the 2.5% level using the Wilcoxin test. These scores are also given in Table 2.

DISCUSSION

It has been shown that the inhibitory process which produces difficulty in learning the central portion of a serial learning task is weaker in people with allusive thinking. It is of importance to know the nature of this inhibitory process. Most workers have considered it to be due, to the setting-up of conflicting associations(16). For ex-

ample, if the items of a series are represented by a-b-c-d, they consider the associations set up between a and c and a and d interfere with the learning of a-b. However, it has been shown by the author in the present study that this difficulty in learning the central portion of a list is lessened after carrying out a difficult learning task, though learning ability is not diminished. This must mean that this inhibitory process is in fact an active one which is weakened by fatigue, and not merely a passive interference of conflicting associations which would still be set up in the above situation.

It is the author's belief that this inhibitory process is that which accompanies attention and produces subjectively the "constriction of the field of conscious awareness" and objectively the electroencephalographic change termed the attention or arousal response. This response is produced when past learning is inaccurate, that is, when prediction fails—when an unexpected stimulus presents itself or when an expected one fails to appear. One of the biological roles of the response appears to be the correction of this faulty learning by setting up excitatory connections between the cortical representation of the unexpected stimulus and that of the immediately previous events and by weakening (with internal inhibitory connections) the excitatory connections active prior to the response, which led to the faulty expectation. Hence attention aids the learning of the items it is focused on at the moment while inhibiting those it was focused on previously. When a series of responses is being learned, attention is focused on one after the other, so that while excitatory connections are established to those in the focus of attention, inhibitory connections are being established between the others.

The author considers it is this inhibitory process accompanying attention which produces the effect measured in the above experiment. The finding that this process is weak in persons with allusive thinking is in conformity with Bleuler's theory as to the nature of the thought disturbance he described and with the author's clinical description of this condition. Furthermore, Malmo and Amsel (17) have shown that the reverse condition—an increased difficulty in learning the central portion of a list occurs

in patients after partial frontal leucotomy, when compared with normals. Partridge (18) found that such patients when concentrating on one activity did not have their attention distracted, even by significant events happening about them. For example, one such patient when engaged in conversation did not notice her kettle boiling over. This suggests the inhibitory process associated with attention is stronger in such people. Hence the finding of Malmo and Amsel is in conformity with the author's theory that the difficulty in learning the central portion of a list is due to the operation of the inhibitory process associated with attention.

It was stated earlier that the author had shown that when a schizophrenic patient shows allusive thinking one of his parents does also. It could not previously be excluded that this familial tendency was due to transmission through environmental contact with the parent rather than being due to a hereditary factor. However, the reduced difficulty in learning the central portion of a word list found in people with allusive thinking can hardly be explained in this manner. Therefore, this finding considerably strengthens the author's hypothesis that allusive thinking is inherited in dominant fashion.

SUMMARY

The observation of Bleuler and Skottowe that certain recovered schizophrenics continue to show a special form of thinking is examined. The author's theory that this thinking is also shown by a percentage of the normal population who have never suffered from schizophrenia is stated and his clinical description of this mode of thinking, termed "allusive thinking," is elaborated.

It is shown that normal subjects with this thinking show less difficulty in learning the central portion of a word list than do subjects without it. Evidence is advanced that this is due to a weakness of the inhibitory process accompanying attention. This is considered to support Bleuler's view that this mode of thinking is due to such a weakness. It is also considered to support the author's view that the familial occurrence of allusive thinking is due to inheritance rather than environmental contact.

SPIRIT POSSESSION IN HAITI

ARI KIEV, M.D.¹

Spirit possession is a phenomenon known to mankind since Biblical times. It refers to a relationship existing between spirits and humans manifested by the possession or incorporation of the human being by the spirit, so that the behavior of the human is taken as the behavior of the spirit. This phenomenon is widely present throughout the world and has been reported not only in Africa and Asia but on other continents as well (10). Perhaps the most complete survey of the subject was undertaken by T. K. Oesterreich who published the classic volume *Possession* in 1930 wherein he considered the phenomenon among primitive races, in antiquity, in the middle ages and in modern times (14). The behavioral character of the phenomenon, most writers agree, has much the same range of appearances from one society to another. Explanations have always differed, however, as have attitudes toward the possessed. Oesterreich has suggested that throughout the ages and at all levels of civilization the phenomenon has been a manifestation of a psychic compulsion.

There is an extensive literature on the subject which has been analyzed in a number of ways. All the theories, metaphysical, theological or psychological have been characterized by a necessity to explain the origin of the new personality emergent in the possessed. Thus the Biblical interpretation concerned notions of the Devil and demons, explanations which persisted in the Western world late into the 19th century. Moving from animistic assumptions of spirit movements, psychological interpretations have sought the explanation in psychic processes. Thus possession has been explained by psychoanalytic theorists as a return of the repressed, wherein Id representatives overwhelm the Ego in a state of dissociation (8, 10). Others, describing the phenomenon in Haiti, have considered it as theatre (13), as a confessional played but not spoken (13), and as a controlled

means for communication normally with the supernatural (6). Perhaps most interesting in the literature on Haitian possession are the personal accounts of individuals who have themselves become possessed. In one subjective account one senses the emphasis placed on the situational stimuli necessary to enter into the trance state of possession (2).

The phenomenon of possession has an important role in Voodoo.² For adepts it is the means by which the Voodoo *loa* (spirit deities) interact with mankind. Through possession of a member of the congregation the *loas* enter the midst of the congregants to punish, admonish, reward and encourage them as well as treat and cure their ills and worries. For the adept the *loas* are recognizable by their appearance, behavior and temperament and other human qualities and characteristics as they are manifested in their human agents (4).

Possession occurs when a *loa* selects "to mount" or "enter the head" of his *cheval* (person possessed). The soul of the person (*gros bon ange*) is replaced by the *loa*. The possessed loses all individuality and becomes the vehicle of the *loa*. All his thoughts and behavior are attributed to the *loa*. Many speak in African dialects, the languages preferred by most *loas*. Some possessed by *Damballa*, the snake god, may perform extraordinary feats of agility and balance, such as tree climbing and branch swinging, often climbing down the trunk head first. Others may hold hot irons in their hands, chew broken glass or walk bare-footed over hot coals. After the possession, most are amnesic for the preceding events (11). As Madame Tisma Innocence, an old and revered *mambo* (Voodoo priest-

² Voodoo, the Haitian folk religion, is derived from a syncretism between African animism and Catholicism. This religion is an elaborate one containing a hierarchical structure of gods, saints and angels, a sacred cult, propitiatory rites, temples and a stratified clergy. It has been practiced secretly for many years because of religious and political pressures but currently enjoys relative freedom, and ceremonies take place under the aegis and approval of public officials.

¹ Henry Phipps Psychiatric Clinic, The Johns Hopkins Hospital, Baltimore, Md.

ess), said: "You loss your consciousness. You have only your body. Your soul is replaced by the *loa*. The *loa* controls your brain, you forget everything."

The disorganized, theatrical and histrionic quality of possession varies from one individual to another, but usually the more experienced individuals have smoother and less chaotic transitions to possession. Exceptions to this exist and depend on the nature of the *loa* possessing the adept so that a violent *loa* will be expected to possess his *cheval* in a violent stormy way. The struggle the *cheval* has in bearing his "mount" is considered as manifestation of this difficulty of "bearing a *loa*." Most Voodoo audiences show great sympathy for the person struggling with a *loa*.

Possession is a usual feature of ceremonies but it is also seen during divination and treatment situations in the *hungan* (Voodoo priests) who invoke the power of their *loas* for these purposes. Occasionally some have observed it in such non-religious surroundings as market places(13). Others have identified the phenomenon outside Haiti occurring in Negroes many generations removed from their African heritage(1).

POSSESSION OF A HUNGAN

For purposes of divination, fortune telling and curing, most *hungan* invoke their *loas* through incantations, prayers and symbolic offerings. In the *houmfort* (temple) and seated before his altar with visitors seated behind him, the *hungan* performs such rituals as reciting the rosary, dropping holy water in patterns of three and lighting candles. He gradually becomes absorbed in prayer, softly singing religious chants and crossing himself innumerable times. There is then gradually and progressively an involvement of his back, shoulder, neck and face muscles which contract first independently and then in unison, the *hungan* progressing to a state of shaking tension where his entire body seems involved. Previously articulate speech turns to grunts and his face is painfully twisted until it is unrecognizable. When possessed, the *hungan* turns and greets his audience with his *loa's* characteristic salutation. Henceforth communication is between the *loa* and the audience. All de-

mands for money, sacrifice, adherence to particular treatment regimens, etc., are requests of the *loa*, not the *hungan*.

The characteristic feature of the *hungan's* possession is the facility and ease of transition to such a state. This can best be attributed to his familiarity and extended experience in entering such states. Save for the changed voice, posture and facies, most *hungans* preserve an amazingly keen awareness and consciousness of the ongoing situation and their role in it, and are able to rely on their vast resources of knowledge and intuitive talents in diagnosing and treating, while being possessed.

Throughout the ceremony the participants depend on the *hungan* who both encourages their self abandonment and controls the limits. The *hungan* himself would seem to be able to do this by virtue of the authority vested in him by his office as priest and undoubtedly because of the belief the congregants have in him. Usually he is a sincere individual. Occasionally, however, he is a psychopathic individual who consciously recognizes the culturally defined needs of his congregants which he manipulates for his own profit. In the case of the sincere *hungan* his possession is mild because of the minimum anxiety he feels in becoming possessed. There is little difficulty for him to control his behavior in this culturally sanctioned role. In essence most *hungans* can readily give up those characteristics defining them as individuals, making themselves into religious personages, and becoming thereby culturally recognizable individuals only. All *hungans* in effect are known by the spirits possessing them and not for their own personality attributes.

POSSESSION OF AN ADEPT

Most Voodoo ceremonies begin as the *hungan* kneeling before his altar invokes the spirits and gradually becomes possessed. During the ceremony, influenced by the dancing, drinking, singing and convivial atmosphere, the other congregants frequently become possessed. Their crises, however, are marked by a greater loss of self control and consciousness than are those of the *hungan*. During one ceremonial, I was able to observe closely the

behavior of a *hunsì* (adept) who became possessed. The main feature of the ceremony was the ritual sacrifice of a goat, without a knife. The *hungan* had donned a bright red military uniform and all the female congregants were brightly garbed in red dresses. The ceremony had been going for several hours and there had been much dancing and drinking.

As the seemingly "drugged" goat fell to the floor and convulsively died, a *hunsì* lurched forward through the crowd and screamed. As if crazed by the death of the goat, she threw herself on the floor beside it and lay dishevelled on the floor, her body writhing and arms and legs flailing. She seemed out of contact with her surroundings and quite unconcerned with the possibilities of self injury. As she stumbled up from the floor her swinging arms brushed closely by the bystanders. She doubled up, her face contorted into a mask of agony, and kicked her feet wildly in all directions. Her head bobbed to and fro and she spit blood from a bleeding nose. She was constrained from further violence by two male assistants who gripped her arms tightly. In time she calmed down and only slowly seemed to regain her senses and composure.

According to the congregants this woman had become possessed by the spirit of the dead goat. The *hunsì's* behavior is indistinguishable from hysterical or dissociative behavior trends. This *hunsì* seemed less comfortable and less in control of her behavior during possession than did the *hungan* and unlike the *hungan* did not retain complete control of her consciousness. However she undoubtedly felt sufficiently comfortable in the role of the possessed to permit herself this self-abandonment.

POSSESSION OF A NON-ADEPT

Not infrequently persons several generations removed from a milieu of Voodoo belief and custom present what to believers are clearly the manifestations of possession. These people, unlike adepts who view such experiences as divine approbation, struggle against these manifestations. They refuse to "accept the call of their *loa*" according to Voodoo belief.

Of interest in regard to this phenomenon of possession outside of Voodoo circles is

the description of a clinical syndrome recently described in Haiti, a syndrome quite comparable to the Voodoo possession and labeled as such by Voodoo adepts.

L'antite clinique la plus fréquente est certainement la psychose aigue rappelant la description de la "bouffée délirante aigue": Installation brutale, confusion marquée, excitation psychomotrice avec conduite, dénudavve et agressive et souvent délire religieux hallucinations visuelles et auditives parfois; le tout de courte durée et ne laissant que peu on pas de deterioration (15).

This description corresponds almost exactly to that of a *hungan* who characterized this illness as a form of possession due to the individual's unwillingness to accept a *loa*. According to Sanseigne and Desrosiers, such patients initially diagnosed as hysterical often deteriorate into chronic schizophrenics after repeated episodes. The *hungan* too, stated that the course was usually short but that occasionally the patient remained "crazy as a punishment from the *loa*."

Of interest is that oftentimes this picture of *bouffée délirante aigue* is accompanied by paranoid elements with religious delusions based in general on the themes of Voodoo and associated with delusions of persecution. Here it would seem that though such individuals are still affected by elements of Voodoo culture which call forth marked anxiety reactions, they are sufficiently alienated from the peasant culture to be unable to use the cultural mechanisms of anxiety reduction through such recognizable role playing.

NATIVE THEORY OF INSANITY

According to popular belief, human beings are composed of the body, the big good angel (soul) and the small good angel (guardian spirit) (7). It is the big good angel which can leave the body without death occurring. This sometimes occurs during sleep. When an individual is ceremonially possessed, the *loa* supplants the big good angel in the head of the individual. Similarly a sorcerer can force the big good angel from the head of a victim using various magical means, with the soul of a dead person or animal causing the in-

dividual to lose his mind, his insane behavior being considered as the manifestation of the dead soul or animal spirit reincarnated in him. This is one of the main causes of supernatural *folie*. The other cause which follows from ignoring the dictates of a *loa* follows a similar pattern, the *loa* supplanting the big good angel and refusing to leave until the individual has accepted Voodoo, although this does not guarantee surcease of the illness.

In both instances of supernatural *folie* the mechanism of replacement of the big good angel by an outside entity producing insanity is identical with the replacement by the *loa* during ceremonial possession. This fact suggests a close tie between genuine *folie* and ritual possession. Further evidence suggestive of a close association between the two phenomena is the oft repeated and commonly acknowledged fact that the first indications that a man is receiving the call to be a *hungan* from a *loa* are indistinguishable from *folie*. If the individual does not accept the call of the *loa* he may be punished in the form of sickness or insanity. Further suggesting the tie is the fact that *hungans* are believed to be more prone to *folie* than anyone else.

DISCUSSION

We have here sketched out three different patterns of behavior and the native theory of insanity all of which share in common the Voodoo explanation of spirit possession. Certain features related to a predisposition to possession seem clear. Firstly, certain personality traits would seem to predispose an individual to possession phenomena. Secondly, early and long enduring observation of the possession of others makes for familiarity and acceptability of it. Lastly, practice and experience in becoming possessed makes for relative ease in negotiating the transition from the normal to the possessed state.

Furthermore, certain features of the syndrome seem clearly definable. Possession is usually characterized by a reduction of higher integrative functions such as articulate speech, social inhibitions and muscular coordination with a concomitant increase of reflex behavior such, as trembling, convulsive movements, muscle twitching, teeth

grinding and sucking movements. In many instances of possession, a sensory anesthesia exists allowing the individual to expose himself to noxious stimuli which normally would be harmful. Such phenomena have been explained in terms of hysterical or auto-hypnotic losses of perception. Injury does, however, often occur according to many Haitian physicians who frequently see burn cases following Voodoo rites (12).

The question arises on the basis of the examples cited as to whether the phenomenon of possession is a form of psychiatric disorder or merely a culturally acceptable patterned role playing. The *hungan* enters into a well-controlled, learned, complex and refined, self-induced trance, through auto-suggestion, probably on the basis of a personal propensity. In the *huns* it has the quality of a dissociative state precipitated and reinforced by a highly charged emotional atmosphere accompanied by an excessive barrage of sound, light and drug stimuli. The last type cited, that of *bouffée délirante aigue* would seem to represent a disorganizing psychotic illness in a culturally alienated individual. These three different explanations, although somewhat reasonable in themselves, fail to consider the unifying cultural aspects of this phenomena. If in Haiti all such behavior is explainable in terms of a single notion of spirit possession, then any discussion of possession should perforce include such a unifying cultural insight.

A concept of a culturally recognized and accepted way of "going crazy" would seem to best incorporate both sets of notions.³ From this viewpoint the role of the possessed is a culturally sanctioned and governed role, applauded in some circumstances (as in ceremonies), vaguely tolerated in other situations (as in market places), and frowned upon or condemned in other contexts and when differing in degree (as in forms of *folie*). It is a role offering opportunity for the expression of much repressed and suppressed feeling and thought. It

³ The concept of a culturally acceptable form of "going crazy" was suggested by Linton's remarks on "patterns of misconduct" (9) and Devereux's remarks on the borrowing from culture by genuinely ill people "the means for implementing their subjective derangement in a conventional way" (3).

provides the poor, downtrodden and oppressed peasantry with an opportunity to enact the parts of gods, becoming for brief periods lordly, omnipotent figures. For the possessed and for observers who can vicariously participate in the possession of others and share the good fortune of being in the company of the gods, possession is a cathartic and spiritually uplifting experience.

Indeed from an early age the peasant child is exposed to ceremonial possessions. He is made aware of the prestige of the *hungan* and the possessed. He sees how applauded are the possessed and learns of their good fortune. Observing the possessions of his elders, a Haitian peasant child grows up with the hope that some day he too will be possessed. As one well educated Haitian told me: "Everyone in Haiti is trying to catch a *loa*" (5). It is obvious that for the non-literate, uneducated peasant "catching a *loa*" by possession is far easier than it is for those more educated, intellectual and sophisticated.

We have presented evidence suggesting that possession is a learned pattern of role playing. The selection of roles and the appearance of the possession are seen as dependent on personal factors. The range of *loa* is so great that a great number of patterns are acceptable as *loa* possessions. This fact accounts for the recognition of the possession in non-Voodoo adepts such as Maya Deren and for the frequent confusion of hysterical or psychotic behavior with possession. Although selection of this role suggests that the role is compatible with the possessed person's personality, it is not in itself sufficient evidence for making a clinical psychiatric diagnosis. The hysteric or psychotic cannot however control the onset, the extent and the completion of his uncontrollable behavior as can the possessed.

The impromptu nature of ceremonial behavior further suggests the conscious role playing aspects of possession. There is frequently much personal imaginativeness expressed by the possessed and much interplay with the congregants who join in the merrymaking, solemnity or other prevailing moods of the ceremonies. The same individuals are possessed year in and year out

by the same *loas*. Occasionally an individual is possessed by several different *loas* in the same evening but this too is characteristic for the specific individual. Each adept is identified with a specific *loa* or behavioral pattern from the time of his or her first possession and it is truly rare for an individual to become possessed out of context, possession being considered expected behavior for ceremonials only.

According to most natives the *loas* prefer "to mount" people who are most like themselves. Thus aggressive individuals are mounted by stormy *loas* and passive mild mannered individuals by gentle and friendly *loas*. Occasionally the opposite takes place as if by "reaction formation." Metraux in his recent work has suggested a number of points which argue against the dissociative quality of the possessions (13). He has pointed out such things as the retention of memory of events during the possession, the self protective caution against bodily harm during possession and the expression of feelings by the *loa* consistent with the possessed person's personal attitudes towards others.

CONCLUSION

Possession as seen in Haiti is a culturally sanctioned, heavily institutionalized and symbolically invested means of expression in action for various ego dystonic impulses and thoughts. It provides a behavioral outlet for much of the impoverished and suppressed peasantry of Haiti. For those who are Voodoo devotees it provides legitimized public roles for private repressed impulses and needs. It serves different needs for different people. For the *hungan* it provides a flexible and recognizable set of ideas which makes possible the translation of private needs into a publically acknowledged religious chosenness. For the *huns* it is an opportunity for the expression of behavior and emotions. The last type of individual "possessed by a *loa*" would seem to be unable to channel his uncontrollable impulses into such an acknowledged and useful role for various reasons, usually ones which have alienated him from the main-springs of the Voodoo cult.

In essence, possession is a useful and culturally sanctioned form of role playing

which serves public as well as private needs and is legitimized only insofar as it occurs in the context of Voodoo and in the correct proportions. For those who are out of touch with Voodoo or for those whose possessions last longer than the ceremonies warrant it is not legitimized and is considered a form of *folie*. The similarity of possession phenomena and psychiatric illness plus the identical explanations for *loa* possession and supernatural *folie* suggests a strong relationship between the two and adds weight to our formulation of ritual possession as an acceptable form of "going crazy."

PATIENT FREEDOM : A VIEW FROM MICHIGAN

IVER F. SMALL, M.D.¹

In the current practice of hospital psychiatry the issue of patient liberty is a pressing and challenging one. The Ypsilanti State Hospital, Michigan, organized a committee under the direction of the superintendent to deliberate and act upon this matter. The crucial concern of this group was that many advances in psychiatry as well as in related fields have forced us to take another look at our administrative policy regarding personal freedom(9).

The state hospital has a long tradition of utilizing administration in the therapy of its patients(2). In the history of the last century one is impressed by the good works of the moral therapists(5). This tradition more recently has been carried on by such men as Myerson(17), Yoder(34), Stanton and Schwartz(24), Wilmer(31), Snow(22), Rees(21), and Jones(10). We have come to see that the milieu in which the patient lives and, in particular, his emotional interrelationships, constitute the hospital restitutive process(16). The committee formed was multidisciplinary and had the obligation to call upon all the resources of this large modern hospital to carry out its functions.

In the past the philosophy of the hospital had been to grant ground liberty to nearly one-third of its patients. Decision to award of this privilege came from the morning medical and nursing staff meetings' consideration of a request by the patient's physician. Home visits were initiated by the relatives but were also considered by this staff. Intermediate areas of freedom were handled on a fairly informal basis, referring to the patient's physician for individual decisions.

A study(7) of the hospital discharge records revealed a high degree of personal caprice in the outward movement of patients to the community. Also, pressure from the increasing demands of our urban area

forced us to consider some method of speeding the turnover of the hospital population. We were to find some system which would effect more carefully planned patient movement but still maintain and increase the therapeutic character of our milieu.

An extensive survey was made of literature dealing with patient freedom in state hospitals(32, 3, 30, 29, 4, 25). Some writers felt that an open hospital was desirable; however, their reasons lay in humanitarian and not therapeutic ideals. Others found advantages in the closed door arrangement. The committee was hopeful that it could find some way that would give the best of both systems, and avoid damage to the milieu structure already developed in our hospital. We contacted 16 other large state hospitals whose problems were similar to our own. All of the hospitals contacted seemed impressed with the need for a solution better than simply opening or closing the doors. All of them had found some partial solution, but were not completely satisfied. Two hospitals in Ontario, Canada, tended to have views comparable with those prevailing in Michigan. Hospitals in New York and California stressed the open features while those in Pennsylvania, Michigan, and Illinois tended to be more conservative. One hospital in Minnesota strongly supported the open ward philosophy. However, the use of open hospitals brought some very readily admitted problems. There were difficulties in training the staff, in keeping patients in therapy, and a large increase was needed in the facilities provided for patients with freedom. Those not embarking on an open hospital operation had problems of limiting patient freedom more than was necessary; they were being forced to find partial solutions for individual patients who really needed an open hospital. Our group was impressed with the reply from the Menninger Foundation, whose philosophy is that freedom should be given as a prescription for therapy.

After considering this problem for a period of months we embraced neither the

¹ Chief of Male Service, Ypsilanti State Hospital, Ypsilanti, Mich. Currently—Assistant Professor of Psychiatry, University of Oregon Medical School, Portland, Ore.

open nor the closed door philosophy. We began to plan for a milieu which would give our patients experience and practice in social living; if we should open our doors they would open to a better adjustment for the patient in the community. In planning this we established 4 major principles.

First was reinforcement of the doctrine already current in the hospital practice that socially responsible behavior was required from the patient. Secondly, the patient's governing body, the patient-council, was to be integrally involved in demanding reasonable conduct from a person receiving liberty. Thirdly, the area of local control of our liberty program required extension. This in practice would give the ward staff a larger number of techniques by which to foster useful social behavior as well as a significantly responsible task for patient-council assistance. Fourthly, we considered our American socio-political structure, which is a composite of personal responsibility, local control and group action for many personal goals. This process is an impelling civilizing factor in our society. Staff-patient organization could make a structure rewarding behavior by modelling such a system. This was effected by the use of a multiple card pass system giving graduated amounts of ground freedom according to individual need.

The types of such cards recommended were: *a.* Therapy card; this card would be granted at the ward and patient-council level. Considerable arbitrary restrictions would be placed on it, but it would be available to the patient upon admission. As his social responsibility increased, further freedom could be considered. *b.* Ground privilege card; this would offer to a suitable patient essentially an open hospital setting, even permitting the use of keys in closed parts of the hospital. Freedom outside the hospital would be considerably restricted. *c.* Honor card; this card would permit an almost unlimited degree of freedom in an effort to rehabilitate the patient. The hospital would be a stable base of operation, which could be used as a day hospital, night hospital or a combination of these as the patient's rehabilitative program necessitated. This card would be limited

temporarily to destroy its reward value for simple hospital adjustment.

DISCUSSION

Placing this program into effect was a prolonged process in a large organization. Of the one thousand staff nearly all were consulted. We did this by personal contact, talks over coffee, in hospital publication of ideas, full dress staff conferences, and briefings of staff by the executive group. Finally, we published a manual giving a complete summary of our work. This careful preparation led to relatively easy acceptance of the plan. When the time came for official inception, active agitation had been initiated by staff to hasten formal executive approval. From the beginning of the operation of the program a major complaint was that it had not gone quite far enough; surely we could do more than this.

Current social psychiatric literature would confirm this major complaint. However, we were very mindful of making only one solid advance. It would be unheeding to plunge without consideration of the hospital as a community with many diverse social forces. Just as unheeding would be to forget the serious import of the concept of mental disorder as a product of social structure. Our attempt was to present a compromise permitting further social development. In creating this portion of a therapeutic milieu we were gratified by the ability of staff-patient groups to seize upon the concept of local control. The best example was a partial opening of geriatric wards simply by granting cards to all patients on the ward.

Perhaps the greatest finding coming from this study has been that patient freedom is only one portion of a total hospital milieu. For patient freedom to be meaningful, the hospital must supply an area in which the patient learns to live normally. Our total program will not be effective until we have individual decision of each patient's individual day with the patient an active participant in decision. Committees are currently working with this problem.

SUMMARY

A statement of policy regarding patient freedom is given by a Michigan hospital. It

is the result of long and considered planning. We have considered both the open and the closed door concepts. In our opinion both present major defects. The basic defect of the open door is "open to what?" or "for what purpose?" The defect of the closed door is that it is not only inhumane but also is not so useful in getting a patient well. We are now attempting to institute a policy that will hopefully combine elements of social living into therapy and rehabilitation. To date, in our setting, the policy appears reasonably successful.

PSYCHIATRIC DISORDERS AND MYXEDEMA¹

FERRIS N. PITTS, JR., M.D., AND SAMUEL B. GUZE, M.D.²

Alterations in mentation have been recognized as characteristic of myxedema since Gull's original description in 1874(1). Delirium, depression, paranoid delusions, and hallucinations were reported as occurring in various combinations by the Committee on Myxedema of the Clinical Society of London in 1888; all their 109 advanced cases evidenced slowing of thought processes and 50% had at least one psychotic manifestation(2).

During the succeeding 60 years case reports of myxedematous psychosis emphasized the clinical syndromes and differential diagnosis(3-6), pathologic picture(7), occurrence after exophthalmic goiter(8) or thyroidectomy(9), hallucinations(10), and therapy(11). In 1947, Asher presented his classic "Myxedematous Madness"(12). The previous articles and 1 fictional reference(13) served to stimulate Asher's interest; he reported his personal experience with 13 examples of this malady which he had encountered in a 2½ year period, stressed their clinical similarity to "the so-called functional psychoses," and speculated that psychiatric hospitals were populated with many unrecognized psychotic hypothyroids. Systematic evaluations of all patients in large psychiatric hospitals identified only an occasional instance of such error(14); so that Asher apparently overestimated the incidence of the disease by reason of unique experience.

Subsequent studies have been primarily concerned with the effects of hypothyroidism on central nervous system function. Scheinberg, *et al.*, observed cerebral metabolic deficiencies in myxedema(15). Brown-ing, Atkins, and Wheeler marshalled the clinical and electroencephalographic evidence that myxedematous psychoses are of

a delirious nature(16). Reitan found intellectual functions uniformly impaired in myxedema(17); Money reported quantitative evidence of "organic" changes on psychologic testing of patients with hypothyroidism(18).

Most recent reports of psychoses in myxedema have appeared either in the general medical or neurologic literature, and indicate that they are clinical entities of a delirious nature differing little in import from myxedematous coma, heart disease, or neuropathy. The current literature on myxedema psychosis seems to indicate that this condition is readily recognizable as a delirium, that psychiatric care is necessary only when the patient's behavior requires closed ward management, and that thyroid extract plus individualized endocrine and cardiac attention constitute the only specific treatment.

Our recent experience with the 3 patients described in detail in this report has demonstrated to us that the psychiatrist must be always on guard that patients may appear clinically depressed or delirious with few, if any, of the stigmata of the underlying myxedema. In addition it seems evident that the mood, behavior, and thought disturbances of hypothyroidism which may persist after adequate thyroid substitution can respond to psychiatric somatic therapy.

Case 1.—Mrs. A. W. (St. Louis City Hospital #M-107779), a 57-year-old housewife, was hospitalized April 11 through Dec. 31, 1959. During the preceding 3 years her family had noted a gradual development of lethargy, weakness, marked irritability, loss of interest in all former activities, retardation, anorexia, constipation, 30 lb. weight loss, crying spells, confusion, inability to concentrate, sleep disturbance, total body alopecia, and auditory hallucinations of a threatening nature.

From Nov. 17 to Dec. 17, 1958 she had been in another hospital where physical examinations, routine laboratory work, electrocardiogram, chest and skull x-rays, and lumbar puncture were reportedly normal. No protein-bound iodine or cholesterol was obtained. Diagnoses were involutional psychotic depressive reaction, alopecia areata, umbilical hernia, and ichthy-

¹ We are indebted to Drs. George Ulett, Herbert Rosenbaum, R. Eugene Holeman, and William G. Becke for permission to use portions of their clinical material.

² Third year resident in Psychiatry, and Associate Professor of Psychiatry, Department of Psychiatry and Neurology, Washington University School of Medicine, Saint Louis, Mo.

osis; accordingly, a course of 10 electroshock treatments was administered which reportedly resulted in a significant improvement in activity, appetite, and interests.

These improvements lasted only a short while, however, and the patient was brought to the City Hospital for further evaluation. There was no past or family history of psychiatric or metabolic illness. The patient had had 5 normal deliveries and had reached menopause at age 45. Physical examination demonstrated total alopecia; dull-bloated facies; myxedema of tongue, face, and pretibial regions; prolonged relaxation phase of myotatic tendon reflexes; cardiomegaly; and inability to stand. She was disoriented for time and place, markedly retarded, and deludedly depressed. Immediate diagnosis of myxedema with consequent organic brain syndrome with depressive symptoms was made clinically.

The hemoglobin was 10.2 gm. per 100 ml., the red-cell count was 4.28 M per cm., the hematocrit was 40%, and the white-cell count was 6200 with a normal differential. The serologic test for syphilis was negative. Urinalysis was normal. Serum carbon dioxide, chloride, potassium, sodium, calcium, phosphorus, and alkaline phosphatase were within normal limits. Fasting blood sugar, non-protein nitrogen, total and fractional proteins were normal.

Protein bound iodine was 0.7 micrograms per 100 ml., cholesterol was 560 mg. per 100 ml., radioactive iodine uptake was 4.3% in 24 hours and the basal metabolic rate was -38%. Urinary excretion of 17-ketosteroids was 3.3 mg. per 24 hours and of 17-hydroxysteroids 0.3 mg. per 24 hours. The electrocardiogram demonstrated low voltage in all leads. Chest films revealed generalized cardiomegaly. Lumbar puncture returned clear fluid under normal pressure, without cells, with a protein of 48 mg. per 100 ml., and a chloride of 140 meq. per L. No Werner test for thyroid response to thyrotropin was done.

Treatment with thyroid extract was begun on the fourth hospital day; initial dosage was 1/8 grain per day, and this was increased rapidly so that by the tenth week she received 3 grains/day. At this time the protein bound iodine was 4.9 mcg. per 100 ml., the cholesterol was 272 mg. per 100 ml., and the basal metabolic rate was -14%. Urinary excretion of 17-ketosteroids and 17-hydroxysteroids rose to 14 and 10.3 mg. per 24 hours, respectively. By the fourteenth week the protein bound iodine was 6.4 mcg. per 100 ml.; the cholesterol was 239 mg. per 100 ml.; the electrocardiogram and chest x-rays had returned to normal. The physical manifestations of myxedema and the dis-

orientation had also cleared by the third month; however, she remained markedly depressed and retarded—so much so that it required 2 hours to perform the mental status examination. Methylphenidate hydrochloride (Ritalin), phenelzine dihydrogen sulfate (Nardil), and imipramine (Tofranil) were administered without improvement; then a course of 12 ESTs was given during the seventh hospital month. Improvement was rapid; the patient was entirely well at discharge. She was maintained on 3 grains of thyroid daily and was well at follow-up 4 months after discharge.

DISCUSSION

The depressive syndrome was so marked in this case that other physicians treated her initially with a course of 10 ESTs. Five months later the diagnosis of myxedema with secondary chronic brain syndrome was made on clinical grounds, and confirmed by thyroid function tests.

Both the thyroid deficiency and the disorientation were corrected by substitution therapy; however, after 5 months of euthyroid state there had been no alteration in the retarded depressive syndrome. A course of 12 ESTs resulted in complete clearing of the retarded depression. This response has been reported in organic depression persisting after elimination of bromide intoxication (19); and there is a general statement concerning such responses in myxedema in the *American Handbook of Psychiatry* (20) without data, however, or textual reference. This case would appear to be a specific documentation of the effectiveness of EST in persistent psychiatric manifestations after the myxedematous patient becomes euthyroid by substitution therapy.

Case 2.—M. G., a 59-year-old white widow, was admitted to Renard Hospital on Dec. 19, 1959 and was discharged Mar. 15, 1960. She and her family maintained that until 8 months prior to admission she had been "an entirely well, happy and very active woman." At that time she began to feel nervous, anxious, and depressed. She felt guilty and was convinced that she had committed some terrible wrong; when an oil well was brought in on her unproductive 50-acre farm she felt "even more hopeless." She developed severe anorexia with nausea and some dysphagia at food ingestion; she lost approximately 35 pounds in the 6 months prior to admission. Severe constipation required "mineral oil nightly in order to have

bowel movement even twice a week." It required large doses of barbiturates to enable her to sleep 2 to 4 hours nightly; in spite of this medication she awakened very early with symptoms of agitation, overwhelming fear and hopelessness, visual blurring, palpitations, tremor, "smothering," and inability to concentrate. Retardation became so marked that she "spent as much time as possible in bed," frequently 20 hours a day; she had lost interest in all her previous affairs and complained of feelings of profound weakness. She also was preoccupied with a "band of numbness around the waist." Ten days before referral she had unsuccessfully attempted suicide by ingesting phenothiazine tablets.

Six months prior to admission she had been hospitalized elsewhere for 1 week. Her complaints were then of nervousness, depression, sleeplessness, and loss of interest. Workup revealed a small asymptomatic hiatus hernia and fluctuating glycosuria which disappeared as she lost weight rapidly.

The patient and her relatives maintained that she had been oriented and alert throughout her illness.

Two years earlier Mrs. G. had been hospitalized for acute cholecystitis and recovered completely following cholecystectomy. There was no other past history of hospitalization, significant illness, or medical attention.

The patient's father was a lifelong alcoholic who died in his 70's; her mother died at 73 of a cerebrovascular accident. Family history of other psychiatric or endocrine disorder was denied.

Physical examination revealed a pale, wasted, graying, agitated, depressed female who appeared at least 15 years older than stated age. Vital signs were normal. Her facies seemed less wasted than extremities; the skin was pale, dry, of normal turgor, and hung from her extremities in great folds. Her voice was somewhat hoarse, of normal pitch and her hoarseness seemed to clear after drinking water. There was moderate kyphosis and increase in anterior-posterior chest diameter but heart and lungs were otherwise clear. Mrs. G. was able to move about unaided; but she evidenced a shuffling-propulsive gait, gross tremor, mask-like facies, drooling and adiadokokinesis. There was no cogwheeling rigidity or abnormality of myotatic deep tendon reflexes. On rapid rising from recumbent position she complained of faintness and dizziness; at these times blood pressure fell from a systolic of 140 and a diastolic of 80 to a systolic of 60 and a diastolic of 0.

Careful mental status examination revealed Mrs. G. to be well oriented. She was tearfully

depressed and admitted constant suicidal thoughts. Her fund of general information, recent and remote memory, insight and ability to reason and abstract were normal. There was no evidence of confusion, thought disorder, hallucinations or delusions (other than depressive ones).

Laboratory determinations revealed normal blood counts and urinalysis. The serologic test for syphilis was negative. Blood urea nitrogen was 15 mg. per 100 ml. Fasting blood sugar was 213 mg. per 100 ml. Protein bound iodine was 2.8 microgm. per 100 ml. Cholesterol was 452 mg. per 100 ml. Twenty-four hour radioactive iodine uptake was 7.7% before and 6.9% after administration of 10 units thyrotropin daily for 4 days. Basal metabolic rate was -9%. Serum bilirubin, cephalin-cholesterol flocculation, thymol turbidity, total protein, albumin-globulin ratio, calcium, phosphorus, alkaline phosphatase, potassium, sodium, chloride, and carbon dioxide combining power were all normal. Lumbar puncture was normal but for a cerebrospinal fluid protein of 147 mg. per 100 ml.

Skull x-rays revealed calcifications of the internal carotids bilaterally; chest x-ray demonstrated only healed fibrocalcific tuberculosis of the left hilum and left lung. Cervical, thoracic, and lumbar spine films demonstrated osteoporosis, advanced osteoarthritic lipping with some cervical bridging and encroachment on root foramina, and generalized calcification of major vessels. Electrocardiogram showed low voltage throughout all leads. Electroencephalogram demonstrated "7-9/second basic resting occipital frequency, reflected anteriorly; somewhat slowed for age 59."

The initial impressions were that Mrs. G. was psychotically depressed, that she had some residual phenothiazine intoxication with parkinsonian features. On the third hospital day however, she became quite confused and was thereafter, disoriented for time and place at least a portion of each day until the protein bound iodine became normal. Shortly after this alteration in her mental status was noted the protein bound iodine and cholesterol determinations were available and the proper etiologic diagnosis of myxedema became evident.

Benzotropine methane sulfonate (Cogentin), 1 mg. b.i.d., had been administered for the parkinsonism during the 3 days prior to the onset of the confusional state. The parkinsonism improved markedly under this medication and remained so even though the drug was discontinued immediately.

Thyroid extract was begun in a dosage of $\frac{1}{4}$ grain daily upon completion of the Werner

test; this dosage was increased weekly by $\frac{1}{4}$ grain increments until daily dosage was 2 grains at which time the protein bound iodine was 6.0 microgm. per 100 ml. and cholesterol was 310 mg. per 100 ml.

Fasting blood sugar remained in the range of 235-300 mg. per 100 ml.; urine sugars were negative until thyroid substitution began at which time glycosuria of trace to 3+ were irregularly found on regular quantitative determinations. Treatment with 1.5 gm. tolbutamide (Orinase) daily resulted in complete disappearance of glycosuria; during the 4 week period prior to discharge the fasting blood sugar was found to be 160 mg. per 100 ml., with 234 and 104 mg. per 100 ml. found at 10 a.m. and 2 p.m. respectively.

During her hospital course the patient gradually became oriented and alert, but developed a perseverative ruminative concern with numerous somatic complaints attributable to her generalized arthritis, and generalized arteriosclerosis. For example, she would complain repeatedly of back ache, chest pain, extremity pain, dizziness with accompanying postural hypotension and anxiety over all these symptoms. Nevertheless her depressive delusions cleared. She required constant encouragement and assistance in occupational therapy and personal toilet. She was reluctant to leave the hospital and its well regulated supportive schedule. She denied depressive feelings concerning her return home, but it was obvious that she would have preferred to stay in the hospital indefinitely.

On follow-up evaluation via phone calls to relatives 6 months after discharge her condition was essentially unchanged; that is she was fully oriented, alert, and much more active. She had never returned to her old active cheerful state, however, and continued with multiple somatic complaints. Repeated attempts to have her return for more specific re-evaluation were unsuccessful.

Discussion of this complex case is in large measure speculative. It seems clear, however, that the onset of her illness was approximately 8 months prior to her hospital admission, that depressive symptoms appeared almost immediately, and that she developed manifestations of delirium only after hospitalization. Her confusion and disorientation appeared only after 3 days treatment with methanesulfonate, a drug which has been known to induce delirium in others (21). Serious clinical consideration of myxedema occurred only after the delirium was

recognized. The diagnosis was made on the basis of laboratory data. Treatment with thyroid extract corrected the myxedema, the delirium, and the severe depressive delusions; but she continued to complain perseveratively of multiple somatic complaints, especially those related to her arteriosclerotic postural hypotension and generalized osteoarthritis. These persistent complaints plus her failure to return to her premonitory cheeriness have led us to wonder whether a short course of electrotherapy might not produce the additional therapeutic improvement described in case 1; thus, it is unfortunate that we have not been able to obtain more adequate follow-up.

Case 3.—H. R. L., a white housewife aged 42, was admitted for the second time to Renard Hospital on Dec. 28, 1959 and discharged Feb. 5, 1960.

In Oct. 1945, she had consulted her private internist for symptoms of depression, crying spells, hyperventilation, multiple phobias including fear of insanity, feelings of hopelessness and anergia, anorexia, sleep disturbance, and ruminations concerning separation from her husband in Naval Service. Physical examination was entirely normal. Impression was "psychotic or psychoneurotic change." She was treated with elixir of phenobarbital and in 2 months was recovered.

In Feb. 1947, she complained of easy fatigability, had a lemon tinted skin as positive physical finding, and evidenced a mild anemia (hemoglobin, 9.5 gm. per 100 ml. and red cell count, 3.5 M per cm.) which responded promptly to iron-liver extract therapy.

During continued follow-up she repeatedly described symptoms of nervousness, dizziness, weakness, cold sensitivity, nausea, and blurred vision. In Mar. 1949, a complete evaluation was stimulated by a thickened, scaly change in the skin; her hemoglobin was 11.5 gm. per 100 ml. with slight macrocytosis (mean corpuscular volume was 107 cubic micra), the bone marrow was normal, the icterus index equaled 25, urinalysis was normal, non protein nitrogen was 40 mg. per 100 ml., and the basal metabolic rate readings were -12 and -16%. No cholesterol was obtained. A diagnosis of hypothyroidism was made and thyroid extract was begun; initial dosage was 3 grains per day, and in 2 months she felt "entirely well."

The patient had maintained herself on 2 grains of thyroid per day until her first Renard Hospital admittance of Mar. 1, 1958 through Mar. 28, 1958, when she gave a 2 week history

of anxiety, worry, anorexia, sleep disturbance, depression, agitation, irritability, psychomotor retardation, and crying spells. She had quit her job and felt her life was hopeless. Physical examination was unremarkable but for the mental status which demonstrated a sad, retarded, tense, anxious, tearful woman who exhibited a fear she had become insane. She was oriented, with normal memory and abstraction, but had some difficulty concentrating. Urinalysis, complete blood counts, cardioli-
pin, electrocardiogram, chest and skull x-ray films were normal. The impression was psychotic depression, and she responded to a course of 6 electroconvulsive treatments. At discharge, her depression had cleared; thyroid was discontinued after a basal metabolic rate of +26 and +30% was obtained. Prior records were not available at that time; protein bound iodine and radioactive iodine uptake were not obtained.

The patient remained essentially well for about 1 year; then, about 8 months prior to the second Renard Hospital admittance she gradually became "less peppy, and then rundown and weak." She became anorectic and lost approximately 15 pounds; she also became quite constipated, anergic, exhausted, and unable to carry on her usual activities. Her memory gradually deteriorated and she complained of difficulty concentrating. Her husband considered her to be again depressed. She had complained of irregular menses, and seemed convinced that thyroid resubstitution would correct this as well as the anergia. On the day of admittance she became confusedly paranoid and called the police to protect her from the family whom she thought were "getting rid" of her. The past and family history was otherwise noncontributory. Physical examination revealed classical features of myxedema: thick, coarse hair; sparse eyebrows; deep-hoarse voice; thick-scaly skin; and markedly prolonged relaxation phase of the uniformly brisk myotatic reflexes. Vital signs were normal. On mental status she was oriented as to time-place-person but seemed confused as to the role of the examiners; her memory was impaired, but evaluation was not precise due to her inability to concentrate as well as her marked retardation. There was no apparent mood depression. Laboratory evaluations revealed a hemoglobin of 8.9 gm. per 100 ml., white cells numbered 8700 per cubic mm. with a normal differential count. Urinalysis revealed a trace of albumin and a few white cells. Residual urine was 100 cubic ml. and produced a luxuriant growth of *E. Coli* sensitive to tetracycline *in vitro*. Serum cardioli-
pin was nonre-
active, cholesterol equaled 448 mg. per 100

ml., protein bound iodine was 1.9 microgms. per 100 ml., fasting blood sugar was 75 mg. per 100 ml., blood urea nitrogen equaled 12 mg. per 100 ml., radioactive iodine uptake was less than 1% in 24 hours. Chest x-ray was normal. Electrocardiogram demonstrated low voltage throughout all leads. Treatment consisted of simultaneous administration of thyroxin and electroshock. The thyroxin was given first in 0.1 and then increased to 0.25 mg. daily dosage; electroconvulsions were administered 3 times per week for a total of 8 treatments. Activity increased markedly within 2 weeks; and the protein bound iodine rose to 6.1 microgms. per 100 ml. after 1 month. The urinary infection cleared with oral tetracycline; and iron-multiple vitamins were employed as adjunctive therapy. She was discharged on 0.25 mg. thyroxin daily and was well 3 months later.

DISCUSSION

The disappearance of Mrs. L.'s psychiatric syndrome without thyroid medication in 1945 and the response of the 1958 exacerbation (acquired while on 2 grains of thyroid per day) to electroconvulsive treatments suggests very strongly that this woman's previous psychiatric illnesses were probably manic-depressive reactions, unrelated to her hypothyroidism. Treatment of the latest psychosis with thyroid alone, initially, would have been preferable; however, her physician's experience with her in 1958 led him to utilize simultaneous electroconvulsive treatments. The possible resistance of depressed affect to thyroid (as in case #1) could not, then, be observed; but complete recovery required only 30 days.

CONCLUSIONS

Asher stated that in "myxedema madness" the physician's proper function is to recognize the hypothyroid state (12). Although he "made the diagnosis on the appearance of the patient and not on mental symptoms—you don't diagnose typhoid by the type of delirium," he also emphasized that it is often exceedingly difficult to make an accurate diagnosis for "the signs and symptoms are not specific to myxedema and any or all may be absent in a particular case."

We have presented clinical reports on 3 unusual myxedematous patients. The first remained retarded and depressed after a 5 months period euthyroid and fully oriented as a consequence of thyroid replacement;

a course of electroconvulsive treatment dramatically cleared her syndrome and she has remained well. This further documents the report noted above of such success with electroconvulsive treatment(20); and we advocate its trial in other patients with persistent psychiatric symptoms after return to a euthyroid state.

The second patient presented as a classic depression in a clear sensorium but became disoriented after 3 days of methanesulfonate therapy for phenothiazine intoxication. She improved markedly with thyroid substitution but persisted in multiple somatic complaints; we have been unable to obtain personal follow-up re-evaluation in order to ascertain the advisability of electroconvulsive treatment for persistent retardation and somatic ruminations.

Case 3 had an apparent manic-depressive depression in 1945 which cleared spontaneously; she developed hypothyroidism in 1949 and was treated with 2 grains thyroid daily until 1958 when a second severe depression cleared with ECT. Following this hospitalization thyroid was discontinued and 18 months later she returned with a myxedematous depressive syndrome which responded quickly to simultaneous administration of thyroid and electroconvulsive treatment. We would have preferred to have reserved electroconvulsive treatments for residual depressive manifestations; however, the clinical response to simultaneous treatment was exceedingly rapid.

SUMMARY

A brief survey of the literature on psychiatric symptoms in myxedema is followed by 3 case reports demonstrating that "Myxedema Madness" may present as seemingly specific organic or functional psychoses, and that psychiatric care may prove vital in the management of these patients. The successful use of EST in psychiatric symptoms resistant to thyroid substitution in myxedema

is reported. The further evaluation of EST in this circumstance is suggested.

NURSING WARD THERAPY AS AN ALTERNATIVE FOR RESTRAINT

KAREL PLANANSKY, M.D., PH.D., AND ROY JOHNSTON, PH.D.¹

A century ago, John Conolly showed that all psychotic patients can be treated safely, with good clinical results, without any form of physical coercion. Furthermore his nursing techniques were fully described as early as 1839(2). Although such transparent rationalizations as the claim that restraints are sometimes beneficial(3, 7) would not be found in current writings, a traditional notion has been tacitly accepted that mechanical restraints are indispensable tools, even if less desirable ones, for the protection of the patients themselves. It is said that they are still needed because other therapeutic measures are inadequate in ward emergencies. A recent revival of interest in abolishing restraints (1, 5, 6, 11, 12, 15) points up the dearth of technical information that could be put to use in actual ward practice.

In this report we describe the nursing techniques as they were evolved in the process of eliminating restraints in an experimental setting. Our first concern was to see whether mechanical controls could indeed be completely abolished on a ward accommodating severely disturbed patients under the typical conditions of service. Must additional nursing care or perhaps new types of psychiatric care be added? What alternative measures such as chemical sedation are required? What practical problems among personnel accompany such a deep change in approaching assaultive patients?

The 65 male patients on our study ward were the most refractory, agitated, combative, and suicidal patients in a 1600-bed Veterans Administration psychiatric hospital. The day shift team includes 1 psychiatrist, 1 clinical psychologist, 1 social worker (part-time), 1 recreation leader, 3 nurses, and usually 10 aides (nursing assistants). Except for nurses and aides, the other staff members were responsible for another 65-bed unit located on the first floor of the same building. Intermittently, graduate nurses were active on the ward as part of an advanced educational program. No ad-

ditional personnel were assigned and no additional funds were requested.

A program of "Nursing Ward Therapy," stressing on-the-spot support and guidance of patients by nurses and aides(13), had already been established on this ward. In Nursing Ward Therapy as practiced here the following aspects are most prominent and indispensable: 1. The nurse is physically present in the dayroom with her patients and accompanies them to other places; 2. The nurse responds to the patient's momentary needs, establishes rapport, and judges daily her patient's mood and receptiveness. The framework of the nurses' activities is not scheduled; spontaneity and improvisation are expected. She listens to patients, talks, walks, works, and plays games with them. The aides are encouraged by example and by consent to imitate the nurses' methods of handling ward emergencies. This approach to the patient is designed not only to reduce tension on the ward but also allows a maximum of contact with healthy people skilled in psychiatric treatment. It is assumed that the patient will emulate the nurses and aides and will relearn some of the normal ways of getting along which have been dislodged by psychosis. It should be noted that the ward psychiatrist and psychologist spend much of their time in the dayroom in unstructured contact with patients to create a therapeutic ward climate.

No formal indoctrination in special techniques was offered the nurses or aides but continual encouragement was given by the ward psychiatrist and psychologist, both in periodic conferences and daily informal meetings. The principles of the program were explained to the evening personnel and periodic reports were received from them. Graphs and tabulations of restraint usage were prominently posted in the nurses' office and served as a basis for discussion and a means of motivating the nurses.

The project was planned in 3 phases:
1. The aim was to involve the nurse directly

¹ VAH, Canandaigua, N. Y.

in resolving ward emergencies with a minimum of physical control; 2. The focus was shifted to the aides and they were induced to rely on their nursing skill more than ever before; 3. An attempt was made to handle ward emergencies entirely without mechanical control or sedation, relying exclusively on Nursing Ward Therapy techniques.

A consistent routine for handling assaults and sudden violent outbursts was introduced as obligatory for the first 6 months (Phase 1). The main feature was an immediate interview by the nurse to decide whether the patient is to remain in restraint and whether a sedative is also necessary (in view of the type of patients, it was an accepted practice for the aides to apply cuffs and belt in extreme emergency before the nurse arrived). The measures decided upon would then be endorsed by the ward physician at the earliest opportunity. The nurse inquired into the circumstances and the likely causes of patient's disturbed states, and instructed the aides as to further management. The aides then could apply the customary restraint (cuffs and belt) in extreme emergency as before. This was done to avoid imposing a sudden change in the aides' traditional role. The Director of Professional Services met with the ward nursing staff to indicate management's interest and to assure the aides that they would not be held responsible for injury to patients caused by failure to use restraints. In the second phase, restraint could not be applied without the nurse's specific order for each instance, even in cases formerly considered exceptional. One month later the third step was added; the nurse was urged to refrain from giving emergency medication. In fact, every instance of restraint had to be reported in a special memorandum to the ward psychiatrist, describing the circumstances and justifying the need.

RESULTS

The use of mechanical restraint, measured in number of applications and in total hours per month declined sharply immediately after the project began. For example, restraints were applied an average of 58 times per month for the preceding 6-month

period while during Phase 1 the average dropped to 21 applications. However, the nurses began to use emergency medication quite freely. During a 4-month period before the study, the monthly average of emergency sedation was 38 doses, while during Phase 1, the monthly average dosage rose to 114 doses.

In Phase 3 (8th through 15th month), when attention was turned toward reducing sedatives, dosage dropped to the pre-experimental monthly average of 37.5. This level remained stable for the last 6 months of the study. At the same time the use of restraints continued to decline until it was negligible. Thus through successive stages, mechanical restraint gave way to chemical sedation and this in turn was apparently replaced by Nursing Ward Therapy. A graph demonstrating the changes in restraint usage is reproduced in Figure 1.

FIGURE 1

During the entire period under study the number of altercations, new admissions, transfers to the ward, number of personnel, and dosage of routine medication dispensed remained essentially unchanged. On this ward ECT is used only exceptionally, in brief courses, and never as a maintenance measure. Tranquilizer drugs are prescribed in very conservative doses; for example, acutely disturbed patients typically receive 300 mg. chlorpromazine daily; in extreme

cases dosage may reach 800 mg. for a few days.

To understand better the reasons for patients' disturbed behavior and also as an educational exercise, the nurse's notes and memoranda required for each application of restraint were examined and causes of patient's distress classified. A number of categories of patient or situations requiring restraint were conspicuous. Most commonly assault was prompted by auditory hallucinations. A more complex, but typical situation was seen in homosexual panic states, where patients struck out in response to either hallucinations or provocative, coarse comments by other patients. Rage reactions, seen in brain damaged patients, were the only cases constituting actual physical danger. In one or two cases restraint was applied to protect the patient's own surgical dressing. Other patients were repeatedly aggressive, mainly to gain attention, and often as a bitter protest against an incapacity recognized through partial insight into their predicament. Although only a few patients could be so classified their outbursts were most repeated. Since they demanded constant attention and reassurance, and were inclined to intellectualize, this group was the most taxing for the nursing staff. It was discovered that although these patients were very annoying and frequently attacked any staff member, they were in fact noticeably quite accepting of Nursing Ward Therapy. Restraint of any kind was never applied to them once they were understood. Finally, and in spite of fairly intimate knowledge of patients, there remained a sizeable group whose unprovoked assaults remained unpredictable and inexplicable.

By the end of Phase 3, the relative size of the groups shifted and restraint was used only in cases of organic brain damage, acute alcoholic intoxication, and one or two non-organic cases whose outbursts were still not explained. Practically all instances of restraint took place during the afternoon shift when a single relief nurse, who was unfamiliar with the patients and whose duties included other wards, was in charge.

DISCUSSION AND CONCLUSIONS

The crucial questions motivating this

venture have been: can the traditional mechanical restraints be discarded without greatly limiting the patients' freedom of action by other agents such as chemical sedation? Even if this can be achieved under the conditions of an experimental effort, is it possible to maintain the necessary level of psychiatric nursing during the daily routine?

These issues were identified in the running debate which took place in the early 1800's in England(3, 8, 9, 10, 14), and later in this country(4). Consistently favorable clinical results under a complete non-restraint regimen were reported (claims that all patients were cured by the new method have a familiar ring). The dramatic improvements were attributed to the carefully devised techniques with which the attendants were instructed to approach the patients in distress(2, 10). The adversaries of this "extreme" in the practice of moral treatment, apparently equally experienced psychiatrists, argued that complete non-restraint was achieved only by substitution of excessive seclusion(3).

In the first phase of the present study, a similar pessimism must have accounted for the transient increase in emergency medications administered on the nurses' own initiative. Evidently, the nurse's syringe had substituted for the aides' cuffs and belt in an otherwise therapy-conscious setting. Only through additional efforts within the structure of an experiment could chemical restraint likewise be brought under control and its minimum limits explored. The nurses observed for themselves that emergency sedation increased when only one regular nurse was on duty: "I didn't have time to stay with the patient and had to give a sedative instead."

Inasmuch as other relevant variables (new admissions, altercations, number of personnel, use of tranquilizing drugs) remained essentially constant throughout the observation period, the virtual abolishment of mechanical restraints and subsequent reduction of sedative medications must be the result of a still more consistent use of the personal, on-the-spot Nursing Ward Therapy. This particular therapy technique will not occur spontaneously but must be introduced with purpose and direction by those

responsible for the ward. In the final analysis, however, success of such a program depends upon emotional acceptance and genuine interest of psychiatric nurses and aides who work daily with their patients.

The level of restraints and sedative medication may be considered a real measure of psychiatric nursing performance. In this concept of measurement, the ideal level of nursing care is seen when physical and chemical controls are rarely used.

Intentionally the study was conducted in gradual stages to give an educational experience to all participants. In the beginning, the nurses took inventory of the restraint practices on the ward. They had the impression that restraints were not used excessively. They were genuinely amazed at the gross discrepancy between what they had believed and the actual restraint practice. When the study was completed they asked themselves: "Why did we need so much restraint before?" Later, the tabulation of chemical sedation was similarly revealing and instructive. Through the act of administering sedative medications the nurse could fulfill a traditional medical nurse's role. This experimental setting gave the nurse an opportunity to abandon some facets of this role and to appreciate more fully—possibly for the first time—the role of a specialist in psychiatric nursing.

We know from spontaneous comments that both the nurses and aides emotionally repudiated the old ways of running the ward, suggesting confidence in their new skills and the likelihood that the changes would be lasting. We also learned that the continual support and personal interest of those responsible for the ward is necessary. Since restraint, which by itself was a source of ward tension, was abolished, patients became more accessible. After the initial strain of getting used to the new techniques, we have the distinct impression that the performance of Nursing Ward Therapy has become an easier and more rewarding task.

SUMMARY

1. The use of mechanical restraint was virtually eliminated on a psychiatric ward of acutely disturbed, combative patients.

2. This was accomplished in a research setting through successive stages designed to be of educational value to the participants.

3. At first, the nurses tended to substitute chemical sedation for mechanical controls.

4. Through a number of informal talks and formal devices (restraint graphs, obligatory written memoranda for all restraint, etc.), Nursing Ward Therapy techniques were finally substituted for both mechanical and chemical restraint. As a result, the ward nurse perceived herself as shifting from a primarily medical role to the role of a psychiatric nursing specialist.

5. Nursing Ward Therapy is presented as the alternative of choice in handling emergencies in large mental institutions.

TRANLYCYPROMINE¹ (PARNATE) IN THE AMBULATORY TREATMENT OF DEPRESSED PATIENTS²

MAX L. LURIE, M.D.,³ AND HARRY M. SALZER, M.D.

Melancholia is one of the oldest recognized mental maladies and it has been treated with a wide variety of methods and drugs. Depression is everybody's concern since it transgresses the bounds of all the medical specialties as well as constituting a definite socio-economic problem. Even then, the actual incidence of depression is not fully recognized since it often strikes in a mild enough form to masquerade as "vague nervousness" or to be hidden by some dominant and attention focusing somatic symptom.

The introduction of the amphetamines some 20 years ago brought new hope for a cure. In 1939 Dub and Lurie(1) reported the beneficial effects of benzedrine sulfate on the mood and psychomotor activity of psychotic patients. In 1953 Salzer and Lurie (2, 3) studied the effects of a hydrazine, but non mono-amine oxidase inhibiting antidepressant drug, isoniazid. Although the benefits of amphetamines and isoniazid proved limited and consequently disappointing, the door was opened for the introduction of numerous more potent chemotherapeutic agents in the past decade including the large group of mono-amine oxidase inhibitors.

Many psychic energizers of varying efficacy have been introduced in the past few years, but none has been uniformly effective. Some have been beneficial in only a specific type of patient with a specific type of depressive reaction(4). Even then, there often is a discouragingly long interval of several weeks before benefit appears. The present study was undertaken to clinically evaluate a new drug which gave promise of being a more effective therapeutic agent.

PHARMACOLOGY

Tranlycypromine, a non-hydrazine inhibitor of mono-amine oxidase, is trans-dl-2-

phenylcyclopropylamine. Chemically it is related to the amphetamines and has the structure

More recently, 10 mg. of tranlycypromine was combined with 1 mg. of trifluoperazine.⁴ This product was introduced because of the realization that depression is often accompanied or masked by anxiety(5). Both drugs were included in this study.

MATERIALS AND METHODS

During a 20 month period 84 depressed patients (53 women, 31 men) were treated. Ages ranged from 21 to 79 years. All were ambulatory and were seen in private practice. Of this number, 57 received tranlycypromine while 27 patients received the tranlycypromine-trifluoperazine combination. In most instances the therapy with tranlycypromine was supplemented by small doses of barbiturates or phenothiazines. Several patients originally given tranlycypromine were later changed to the combination drug. The duration of treatment varied from 1 to 19 months except in 5 instances where a side effect forced an earlier termination of therapy. Eight patients received concurrent electric shock therapy while 35 had required shock therapy either for a previous episode or before starting with tranlycypromine. The average duration of the depression prior to therapy was 3½ months. All of the subjects exhibited psychomotor retardation with inability to function adequately from a vocational or social standpoint.

Fifty-one patients had psychoneurotic depressive disorders, of which 26 were endogenous and 25 were reactive. The remaining 33 patients had psychotic depressions, including 8 manic-depressive reactions in the

depressed phase. Patients with demonstrable organic brain disease or depressive manifestations of schizophrenia were excluded from the evaluation.

During the earliest phase of the evaluation, a few patients received initial doses of 10 to 15 mg. of tranylcypromine a day. It was soon apparent, however, that initial doses of 30 mg. a day produced a much more rapid and dramatic onset of improvement. Consequently most patients received initial doses of 10 mg. of tranylcypromine three times a day, plus appropriate doses of a tranquilizer, usually either prochlorperazine, meprobamate, or a barbiturate. In some patients it was desirable to alter the dosage level relatively quickly, but in general, the initial dosage was maintained for an average of 4½ weeks. Subsequent decreases were made in accordance with the patient's progress but usually not for at least 4 weeks.

RESULTS

The results were evaluated in terms of subjective and objective improvement of the mood and psychomotor state. Symptomatic improvement was sought but, as stressed by Lesse(6), emphasis was placed primarily on the individual's ability to adapt to the routine vocational and social responsibilities of everyday life.

On this basis the results were almost identical in the group treated with tranylcypromine and the group treated with the combination of tranylcypromine and trifluoperazine. Consequently, the results in the two groups will be considered together.

Marked improvement occurred in 46 instances while the results were rated as moderate in 16 others. Ten individuals showed only minimal or transient improvement while 12 showed no benefit after 3-4 weeks of therapy. Combining these results, significant benefit was derived in 62 cases (74%) while 22 cases (26%) were considered failures. Lending credence to these results, and serving as a type of control, was the fact that the percentage of improvement obtained independently by each of the authors in his own series, was virtually identical.

Benefit from tranylcypromine appeared in an average of 9 days when a large initial dose was used. The average with the com-

bination of tranylcypromine and trifluoperazine, however, was 7 days. With both drugs, a few patients began to show signs of improvement after only 2 days of therapy while in some cases, the improvement did not appear until the third week. The delayed response, however, bore no demonstrable relationship to ultimate recovery.

Where the dosage was reduced prematurely and some depressive symptoms recurred, a prompt reversal was achieved when the dosage was temporarily increased. In 4 cases there were relapses 3 to 7 months after therapy had been discontinued. In each instance prompt improvement resulted when therapy with tranylcypromine was re-instituted. Their course was similar to their previous response even though it was usually treated with 20 mg. daily rather than 30 mg. Perhaps this may have been the result of initiating therapy relatively sooner after the reappearance of depressive symptoms.

SIDE EFFECTS

Initially blood counts were made routinely on all patients, but when no deviation from the normal was found in our patients on repeated examinations, nor reported by other investigators(5), this procedure was discontinued. Likewise, no instance of jaundice was encountered nor, to our knowledge, has any case been reported(5).

Most of the patients (62%) experienced no side effects. In 14 instances there were mild, but insignificant side effects. They were similar for both drugs: dry mouth, restlessness, dizziness and insomnia. The latter usually responded quickly when the last dose was given by 3-4 p.m. or when a mild sedative was added. Dizziness was overcome by giving the drug at bedtime, strangely enough, without producing any insomnia. With the combined drug, some drowsiness was also encountered.

More significant side effects included a diffuse macular skin rash which occurred in 5 cases and a severe devastating and disabling headache in 2 cases. The skin rash gradually disappeared when the drug was discontinued and did not require any specific ancillary therapy. The headaches were self limited, lasting only a few hours. They were generalized, very severe, and were accompanied by extreme agitation, restless-

ness, apprehension, and a transient elevation of blood pressure. They occurred after the ingestion of a heavy meal but produced no nausea or vomiting. In both instances they occurred after about 10 days of therapy. In each instance therapy had to be discontinued.

CASE REPORTS

Case 1.—A 51-year-old married man gave a history of mood swings, mostly of depressed nature, since the age of 20. These depressions had become more severe in recent years with each episode requiring hospitalization and electric shock therapy. Even then, improvement was slow and he usually missed 4 to 6 months of work. Chemotherapy was of minimal value in these episodes.

Like all previous episodes, the present one began rather suddenly and was characterized by a severely depressed mood, crying, marked psychomotor retardation, hysterical and impulsive behavior, and insomnia. He took an overdose of sleeping pills, apparently in a suicide attempt, but without any after effects. He was placed on tranlycypromine 10 mg. t.i.d. along with small doses of prochlorperazine and glutethimide. During the first 3 days of therapy, he took an entire bottle of 50 tablets of tranlycypromine at unknown intervals in unknown doses. No untoward side effects were observed. However, therapy was discontinued for one week and then he was again given 10 mg. of tranlycypromine t.i.d., plus a tranquilizer. One week later he showed definite improvement but was still depressed.

After 2 weeks of treatment, he returned to work on a part time basis and within 6 weeks was on a full time basis. About one month after therapy was begun the symptoms had largely disappeared and he was no longer using any sedative. The tranlycypromine was reduced to 10 mg. b.i.d. and was continued for 4 months. It was then reduced to 10 mg. once daily for 3 weeks and then discontinued. When seen 6 months later, he was adjusting well without any recurrence of symptoms.

Case 2.—A 25-year-old married woman gave a history of hysterical outbursts and depressive symptoms of 4 months duration. She was tense, tremulous, restless, and cried frequently. Her appetite was impaired and she had lost weight. She was afraid to be alone because of a fear that she was going insane and would kill her 3 children. She entertained thoughts of suicide, was unable to perform her household duties, and showed marked psychomotor retardation.

She was given the tranlycypromine-trifluoper-

azine combination, one tablet t.i.d., and 4 days later some subjective improvement was noted. At the end of one week she was less irritable, felt calmer, was eating and sleeping better, and felt less depressed. The drug was reduced to one tablet b.i.d. and she continued to improve. There were no further hysterical outbursts, and all symptoms of depression disappeared. Two months after therapy was begun, the drug was reduced to one tablet a day and her improvement has been maintained.

Case 3.—A 51-year-old nurse gave a history of 5 previous depressions, each of which responded to electric shock therapy.

Her current depression had been treated unsuccessfully with another course of shock therapy and she continued to be despondent and unable to work. The presenting symptoms were anxiety, apathy and pessimism, obsessive erotic thinking, inability to concentrate, and homicidal ideation. The somatic symptoms of insomnia, poor appetite, tachycardia, and tremulousness were relieved by a high protein, low carbohydrate diet. Along with this diet she received various sedatives, two antidepressant drugs, and supportive psychotherapy, but without any significant improvement.

After 3 months of this therapy, and when the patient was feeling that recovery was impossible, treatment with tranlycypromine 10 mg., t.i.d. was begun. Twelve days later she described her attitude as follows: "I felt like my old self again. I felt compelled to do my work." The medication was reduced to 10 mg., b.i.d. Six weeks after tranlycypromine therapy was instituted, she returned to her professional duties.

Because she resented being dependent on any medication, periodically she would stop taking the drug. In each instance, she again became depressed within 7 to 14 days, but the depression was alleviated within 3 or 4 days after resuming the tranlycypromine.

Case 4.—A 59-year-old man gave a history of a depression 10 years ago which responded to a series of electric shock treatments. Another depression 8 years ago failed to respond materially to EST, or to treatment with 12 different antidepressant drugs given over the course of the next 7 years.

When the present study was undertaken, he was significantly depressed, disinterested, forgetful, unable to concentrate, seclusive, and given to "day dreaming." Tranlycypromine, 10 mg., t.i.d., was administered.

Nineteen days later, he was greatly improved. He stated, "It took the treatment two weeks before it had any effect. I could feel it wanting to work. It seemed like there was a

closed curtain there. At the end of two weeks I began to penetrate that a little bit. At the beginning of the third week I noticed the improvement was prolonged, and each day it lasted longer until I felt well all day."

The dosage of tranylcypromine was reduced to 10 mg. b.i.d. on the 19th day. During the next 12 months repeated efforts were made to decrease the dosage further, but this proved impossible without experiencing a return of the depressive symptoms. At the end of one year of therapy he continued to be symptom free, but was still taking 10 mg. of tranylcypromine b.i.d.

DISCUSSION

The 74% improvement rate with tranylcypromine represents a significantly higher improvement rate than might have been expected in a similar period of time from psychotherapy alone. Likewise, the rapid onset of improvement in 7-9 days, although not as rapid as the 5 day average reported by Petersen(7), constitutes a specific drug effect.

The distinctly more rapid onset of benefit with the tranylcypromine-trifluoperazine combination in 7 days versus 9 days with tranylcypromine itself, despite the concomitant use of barbiturates or phenothiazine derivatives with the latter, suggests that part of the therapeutic result may be due to the action of trifluoperazine. However, the combination drug was found to produce benefits not obtainable from either tranylcypromine or trifluoperazine alone. The combination also eliminated the agitation and restlessness often encountered during therapy with tranylcypromine alone.

In 4 cases it has proved impossible to discontinue the drug without the recurrence of depressive symptoms, although the drug has been taken in small doses for as long as 12 months. Each time this was attempted, these patients found that only restarting tranylcypromine would help them.

Our experience has indicated that the best and most dramatic results are obtained with an initial dose of 10 mg., t.i.d. The drug should be decreased slowly, usually over a period of several months. This tends to

minimize a recurrence of any of the depressive symptoms.

Of the 22 cases who failed to respond to tranylcypromine, 9 failed to respond to any subsequent form of therapy while 7 patients recovered on therapy with other antidepressant drugs or EST. Contact was lost with the 6 remaining failures.

The incidence of improvement in each of the diagnostic sub-groups of depressions was analyzed. This failed to reveal any statistically significant selective effect of the drug.

SUMMARY AND CONCLUSIONS

Tranylcypromine is a safe and potent mono-amine oxidase inhibitor which, when used in combination with sedatives, produced improvement in 74% of 84 ambulatory depressed patients of both psychotic and psychoneurotic types. The onset of benefit was rapid, occurring within an average of 7-9 days. The improvement was more rapid and more dramatic when the drug was combined with trifluoperazine. The incidence of significant side effects was low. No case of blood dyscrasia or jaundice occurred in our series. Some of these cases have been followed for over one year and have had no relapse.

RESULTS OF SIMULTANEOUS ABRUPT WITHDRAWAL OF ATARAXICS IN 500 CHRONIC PSYCHOTIC PATIENTS

L. N. JUDAH, M.D., Z. M. JOSEPHS, M.D., AND O. D. MURPHREE, Ph.D.¹

For a number of years most psychiatric hospitals have given various forms of tranquilizers in varying doses to many patients. Psychiatrists have made all possible checks to assure themselves that the patients were not being harmed and over the years little evidence of damage has been found. The reports of disturbing, or even dangerous, side effects have become fewer and in many of the newer tranquilizers they are even less frequent than in the older ones. Nevertheless, one wonders if the continued long-term use of these drugs might not some day cause unexpected and even dismaying clinical results. From the standpoint of the clinician it would seem logical to suspend the drugs for a period from time to time if no harm will come to the patient.

A great deal of work has been done on the effects of the withdrawal of drugs. Both gradual and abrupt withdrawal have been attempted. Usually these studies have been with comparatively small groups which were made the subject of intensive clinical or psychological observations and often these have been balanced by well conceived and well controlled groups. We have seen no studies involving a relatively large number of patients who had withdrawal of their ataraxics more or less simultaneously. It was felt that information was needed by the clinician about the results of such group withdrawals, both in the individual patient and the effect on his environment.

When drugs were removed abruptly, particularly if they had been given in sizable amounts over a long period of time, there had been reports of disturbing reactions(1). On the other hand, we have on many occasions seen patients abruptly removed from large doses of tranquilizers because of intercurrent medical or surgical necessity, or because the patient may have eloped without any serious symptoms resulting.

We have given considerable thought to the contradiction between the facts in the

preceding paragraph and the reports of severe withdrawal symptoms. It seems that the most logical explanation was that any research project necessarily involves a certain amount of expectancy, and this might account for the discrepancies. For example, one author reports 17 occurrences of morphine-like withdrawal symptoms in 28 patients(1). He had given these patients placebos, but he was never able to persuade them that these were not a new and more powerful drug. Other series have been studied with elaborate and well conceived batteries of psychological tests and it is entirely possible that the psychotic might well take these to be a sign of either hate or of affection.

With the above in mind we conceived the project of removing a relatively small number of patients from tranquilizers by simply stopping the drugs. This was done with a minimum of discussion with either patients or personnel. We selected a hospital industry ward and a maximum care ward. These 2 wards adjoin each other and the staff physician in each case has frequently served the other ward and was rather well acquainted with the patients and the personnel, and was in turn well known to them. All of the patients on these two wards who had been given tranquilizers continuously from 2 to 5 years and who were considered in satisfactory control had the drugs removed. There were 33 patients chosen on the maximum care ward and 54 on the hospital industry ward. Since the number of patients involved was small, it was felt that one or the other of the 2 staff physicians could always observe them closely. The drugs withdrawn were chlorpromazine (Thorazine) in 40%, prochlorperazine (Compazine) 23%, trifluoperazine (Stelazine) 17%, and in lesser percentage, thioridazine (Mellaril), reserpine, Tentone, and meprobamate. The trial lasted for 5 months, beginning in December, 1959.

Because of the opportunity for close ob-

¹ VA Consolidated Hosp., N. Little Rock Div., Little Rock, Ark.

servation we are giving the figures for this group in some detail.

At the end of 5 months the maximum care ward still had 35% of the original group off tranquilizer medication; the hospital industry ward 45.5%. On this ward the first patient was returned to treatment in 2 days, and the last patient to be returned was restarted on the 117th day. Thirty-four percent of the hospital industry ward patients were returned between the 7th and 8th week, and 62% of those returning on this ward re-commenced medication between the 7th and 15th week. Only 1 patient returned later than the 15th week. On 68 Upper, the more acute maximum care ward, the first case returned to treatment on the 6th day, and 27% returned between the fourth and sixth week. One case lasted 152 days before returning. On 68 lower, the less acute maximum care ward, the first case did not return to medication until the 5th week and the last return occurred within the 22nd week. The largest number, 30%, returned between the 5th and 6th week.

On both wards the most usual symptoms requiring the re-starting were hyperactivity, muteness, loss of pride in personal appearance, decreasing contact and threatening behavior and/or verbalizations. A few patients either commenced or increased hallucinations.

The most severe symptoms occurred in 2 patients, and were almost identical. Both were on chlorpromazine, one was receiving 1200 mgm. a day, and the other 300 mgm. Both complained of malaise and insomnia within 24 to 48 hours after the drug was stopped. The 300 mgm. case showed considerable diaphoresis almost at once and treatment was restarted after 7 days. The 1200 mgm. case began to complain quickly of general malaise, but the diagnosis was complicated by a complaint of dysuria and the discovery by the Genito-Urinary Service of a prostatitis around a prostatic calculus. This patient showed a most severe diaphoresis in 28 days and was returned to chlorpromazine in 33 days. All symptoms except the dysuria in the second case disappeared promptly after the ataraxics were restarted.

When the smaller intensively studied group was successfully withdrawn we

turned to a larger study, in which 519 patients, nearly one-third of the non-medical psychiatric population at the hospital, were removed from tranquilizer medication for 90 days. Wards used in this study were 2 open wards, 3 partial privilege wards, and 1 which was geriatric with some younger regressed schizophrenics. Typical dosages in these patients were 300 mgm. or 600 mgm. of Thorazine per day or 30 mgm. Compazine. Meprobamate daily dose never exceeded 1200 mgm. per day. Their return to medication in the ensuing period showed a peak at 30 days with a large number, approximately 28%, still off at the end of the period. There were a few reports of nausea, vomiting and/or diarrhea early in the trial. None was severe, and few needed medication. All subsided promptly. Otherwise, withdrawal symptoms resembled those of the smaller group. However, some of these symptoms occurred in non-medicated patients as well, and in patients whose medication was not withdrawn, so that we feel it would be easy to overemphasize the expectancy of these symptoms. Where seizures have been reported in the literature with meprobamate withdrawal, the dosages have been much higher than we used. During the period there were 6 of the 519 patients sent to the maximum care ward. One had become intoxicated on partial privileges and 2 had been absent without official leave.

The reaction of the ward personnel was both interesting and a problem. On all wards the nursing assistants were quite doubtful of the wisdom of the attempt. This is understandable in a hospital which has never had a seclusion room and which prides itself on the non-use of restraints. As the failures began to return to medication this fear died away, the talk of a "change in ward climate" was no longer heard, and at the time the studies were terminated those who were not returned to medication were considered to be normal members of our ward communities.

CONCLUSIONS

It was the opinion of the staff physicians who had known the patients well for a long time, that there was probably some worsening in such matters as increase or beginning of hallucinations, poorer eating habits, in-

creased apathy, restlessness, slovenliness, and general deterioration. The few patients sent to the maximum care ward indicates that hyperactivity was never a pressing problem. The overall impression was that the diseases had merely resumed their symptomatic courses when the protection of the tranquilizer was removed. On the whole exacerbated symptoms subsided readily when medication was reinstituted. Transfers to the maximum care ward did not rise to an appreciable extent (6 in 3 months).

SUMMARY

It is our opinion that the sudden withdrawal of tranquilizers from chronic psychotics living in a protective and reasonably permissive ward atmosphere will do no apparent harm to their condition in the majority of patients for a period ranging up to 5 months. Withdrawal symptoms were few, mild, and easily controlled, and asocial conduct usually subsided readily when the drugs were readministered. Drug intake as measured by duration, or dosage, or type

of drug does not seem to be a factor as to how long a case can remain off medication socially. Neither do diagnosis, or apparent duration of illness, or age, except that those within the geriatric period seemed to remain off medication for the 90-day period in somewhat larger percentage. The results of this experiment seem to confirm a 1954 study(2) by a group at this hospital which found that clinical response and the pattern of resistive isolation in the Lorr Scale were the main improvements to be expected following the use of chlorpromazine and reserpine—and the present authors feel that this may well be true of all tranquilizers on this type of patient.

CLINICAL NOTES

(The Clinical Notes report the findings of the authors and do not necessarily represent the opinions of the Journal.)

THE EFFECT OF AMPHENIDONE (DORNWAL)¹ IN ANXIETY STATES: A MULTI-BLIND STUDY

H. AZIMA, M.D., DOROTHY ARTHURS, R.N., AND A. SILVER, M.D.²

Since the effect of "major tranquilizers" on anxiety states has appeared to be equivocal, a continuous attempt has been made to develop specific antianxiety and antitension substances. Amphenidone (1-m-amino-phenyl-2-pyridone) was introduced as such a substance (1, 2, 3). The present study was undertaken to systematically investigate this contention.

The research design was what we have designed as "multi-blind" (4) because it contains two characteristics: 1. Pharmacotherapeutic blind unit. This consists of a research service at the Allan Memorial Institute where all medications are distributed solely by the research nurse, under the supervision of the chief of the service, without the knowledge of the research team (7 psychiatrists, 1 psychologist, 1 social worker, 1 occupational therapist and 2 ward nurses). In this unit at any given time an average of 5 new drugs and 5 placebos are being used, to the effect that there is an ignorance of the pharmacotherapeutic regime at several levels. 2. Multiple observer assessment. The final evaluation of the drug effects is the pooling of observations of different members of the team. The drugs are administered at random. A simple rating scale was devised to evaluate anxiety, consisting of behavioral (autonomic signs, restlessness, irritability) and experiential indices (tension, anxiety, discomfort, jitteriness, "nervousness"). Complete disappearance of behavioral and experiential indices were designated as marked, and complete behavioral and partial disappearance of indices as moderate improvement. Slight improvement was included in nil category.

Amphenidone was administered orally in the above setting to 40 patients, with an average daily dose of 3700 mg. (maximum 6400 mg., minimum 1600 mg.) for an average period of 3 weeks. There were 22 males and 18 females with an average age of 37½ years. Diagnostically they consisted of 28 neurotics (10 anxiety states, 1 obsession, 4 mixed states, 10 depressions and 3 addictions) and 12 psychotics (1 depression, 11 schizophrenics). The major symptom in all cases was anxiety and tension.

Placebo was administered to 40 other patients for an average period of 3 weeks. There were 20 males and 20 females with an average age of 36. Diagnostically they consisted of 28 neurotics (10 anxiety states, 1 obsession, 6 mixed states, 10 depressions and 1 addiction) and 12 psychotics (1 depression and 11 schizophrenics).

RESULTS

In amphenidone group 9 out of 28 neurotics and 6 out of 12 psychotics showed significant (moderate to marked) improvement. In the placebo group, 2 out of 28 neurotics and 1 out of 13 psychotics showed moderate improvement. The Chi Square (X^2) analysis of the results indicated that the response to amphenidone in neurotic patients was statistically significant at slightly better than 0.05 level ($0.05 > P > 0.02$). In psychotic group there was only a tendency to significance ($0.10 > P > 0.05$), due to the small number of patients used.

Side effects were very minimal in amphenidone group and consisted of mild fatigue and drowsiness in 9 patients, slight dizziness and headaches in 6, hand tremor in 2 and nausea and vomiting in 2. Biochemical tests (liver function, W.B.C., urine analysis, and BP and TPR remained within normal limits.

¹ Dornwal is manufactured by Maltbie Laboratories Division.

² McGill University, Department of Psychiatry and A.M.I.

The general impression was that amphenidone was a mild to moderate and safe anti-anxiety and antitension substance and suited mainly for neurotic anxiety reaction.

A CLINICAL EVALUATION OF FOUR ANTIDEPRESSANT DRUGS (NARDIL, TOFRANIL, MARPLAN, AND DEPROL)

PAUL C. AGNEW, M.D., IRVING D. BARAN, M.D., HOWARD J. KLAPMAN, M.D.,
F. THEODORE REID, JR., M.D., JERRY J. STERN, M.D., AND
ROGER H. SLUTSKE, M.D.¹

The purpose of this study² was to evaluate the effect of four antidepressant drugs,³ on the clinical picture of depression.

The study covers the relatively short period of 3 weeks since: 1. We have baselines of expected response to established treatments such as EST, tranquilizers, support of milieu, and doctor-patient relationship for this period which could furnish comparison; 2. Longer periods (6-8 months) tend to confuse the question of attributing result to the drug, other concurrent therapies, or natural course of the illness; 3. In order to seriously challenge established therapies, the drugs would have to produce discernible clinical improvement in a 3-week period.

Subjects were selected on the basis of depressive symptomatology rather than of diagnostic category. Excluded were: 1. Patients with liver or kidney disease; 2. Patients who required the immediate use of established methods such as ECT (severely depressed, suicidal patients who refused food). A total of 26 patients were studied over a period of 6 months.

The study was based on frequent close

observation of changes in the clinical picture. From his own examination and information from ward personnel, the resident filled out an evaluation form every third day, beginning with a 14 day pre-treatment period to get a clinical baseline and to pick up any trend of change before the drug was started. All subjects were receiving indicated regular treatment such as individual and group psychotherapy, occupational and recreational therapy. Patients were then placed on a drug for a 3-week period. As each form was completed, the resident turned it in, so as not to have it for reference in filling out subsequent forms. At the end of the 3 weeks' treatment period there were 13 evaluation forms for each patient describing his clinical picture over a period of 5 weeks, as shown in the following example.

EVALUATION FORM

Patient's Name _____ Physician _____
Day of Pre-treatment evaluation 1 3 6 9 12
Day of treatment (circle) 1 3 6 9 12 15 18 21
Patient's age _____ (1) Weight _____ (2) B.P. _____
(3) Hours of sleep _____
(4) Bowel functioning: _____
(5) Side effects: _____
(6) Appetite and feeling about food: _____
(7) Participation in activities: _____
(8) Level of anxiety or agitation: _____
(9) Thought processes and content: _____
(10) Mood—subjective or objective: _____

sent to the hospital pharmacist who assigned one of the 4 drugs or placebo in rotation. All drugs were sent to the ward under a code name, and were taken orally. No one involved in the study knew which drug a patient was receiving. Only after all the data were analyzed did we break the code.

The data on the 13 evaluation sheets on each patient describing features of the clinical picture are traditionally regarded

as especially pertinent in depressions. They depended on the clinical judgment and observation of the residents. Thus, clinical observation rather than check sheets or rating scales is the yardstick which has always been the determinant of practice, of accepting new treatment methods or discarding old. For this reason, in spite of its imprecision as a tool for scientific measurement, it was used in this study with the controls and balances built into the experimental design.

TABLE 2

DRUG	MUCH IMPROVED	SLIGHTLY IMPROVED	NO CHANGE	WORSE
Marplan		2	3	1
Tofranil	2	2	1	1
Deprol		4	1	
Nardil	2	1		1
Placebo			4	1

As mentioned above the patients in this study were receiving the usual therapies both before and after receiving the drug. Thus, when the drug was started, we were in a position to observe whether the baseline trend seemed to be significantly altered in a 3-week period.

We decided to graph the data on a simple three-point scale indicating degrees of severity of clinical depression with the upper point on the scale indicating significant improvement. The graphs, made up by an IBM consultant, merely represent the descriptive statements of the evaluation sheets. We then exercised two checks: 1. We asked each resident if the graph represented what he had intended in his evaluation sheets; 2. We had a consulting psychiatrist go through the nurses' notes on each patient and report if the description of change in clinical picture correlated with that indicated by the graphs. Both checks supported the accuracy of the graphs.

After we had thus determined a final evaluation of clinical change for each patient, we broke the code and determined the result by drug.

When analyzed in this way, our data are inconclusive, even when keeping in mind that we were directing the drug against depression regardless of diagnostic category. Certainly numbers are too small to warrant differentiating between the drugs in any conclusive manner. We will leave it to the reader to conclude any differentiation. Our only conclusion from these data is that all 4 antidepressants drugs showed better results than the placebo. This would seem to have some significance, even with small numbers, in a double-blind study.

If we present the data in terms of num-

bers eliminating diagnostic category, this differentiation between the 4 drugs and the placebo seems more striking.

Conclusions: 1. None of the antidepressant drugs is a wonder drug in the dosage and time period for which we used them, but they have some favorable influence on depressive symptomatology. 2. Objective, controlled clinical evaluation of drugs in psychiatry is difficult because of (a) the imprecision of our measurements, (b) the many variables (such as effect of individual psychotherapy, nurse-patient relationship, just being in hospital, etc.) which are hard to evaluate (not to speak of control), (c) the massive effort involved in dealing with statistically significant numbers in a study based on intensive clinical observation, (d) the inaccuracy accrued when one deals in large numbers using infrequent casual clinical observation, and (e) uncertainties as to natural course of illness when long time-span is involved.

Nevertheless, controlled clinical evaluations of new drugs are essential in order to maintain a rational treatment.

Drug courses used in the study:

1. *Marplan* (Analog of Iproniazid, an amine oxidase regulator). Dosage: 10 mg. p.o., t.i.d. for 7 days; 10 mg. p.o., b.i.d. for 14 days.

2. *Tofranil* (Imipramine, G22355, MOA inhibitor). Dosage: 25 mg. p.o., t.i.d. for 21 days.

3. *Deprol* (Meprobamate plus benadryzine hydrochloride). Dosage: 1 tablet p.o., t.i.d. for 21 days (400 mg. meprobamate plus 1 mg. benadryzine hydrochloride).

4. *Nardil* (MOA inhibitor). Dosage: 15 mg. p.o., t.i.d. for 21 days.

CASE REPORTS

THE PHOBIC ANXIETY-DEPERSONALIZATION SYNDROME

I. PIERCE JAMES, M.A., D.P.M.¹

Roth(2, 3) described as "the phobic anxiety-depersonalization syndrome" a group of symptoms which he had noted occurred frequently in individuals of immature and dependent, yet obsessively driving and routine-bound personality under certain types of stress. He regarded the condition as a "pan-neurosis" often dominated by anxiety, depression and depersonalization; but a "distinct entity," to be distinguished from depressive illness, *etc.*

The essential features are depersonalization and a characteristic pattern of phobic anxiety; often a fear of leaving familiar surroundings, of being alone in crowded places, *etc.*, and of fainting, losing control, harming others, *etc.* Vaso-motor disturbances, hypochondriacal preoccupation, obsessional symptoms and a neurotic type of depression (often labile but occasionally severe) occurred in the majority of patients. In nearly half of the cases there were "not only unreality feelings, often of an episodic nature, and *déjà vu* phenomena but additional symptoms suggestive of dysfunction in the temporal lobes or related structures in the limbic system. These included metamorphosis, panoramic memory, intense hypnagogic hallucinations and the interesting closed-eye hallucinations ('private cinema phenomenon') often described in experiments with hallucinogenic drugs and in pre-delirious states."

Roth placed great emphasis on the pre-morbid personality and on the precipitating life-stress. The patients were on the one hand conscientious, scrupulous, earnest, routine-bound and anxiety-prone—in other words mildly obsessional—while on the other hand they were dependent and emotionally immature to a marked degree, intense and often exclusive of social contacts outside the immediate family circle. Most of the women were frigid but strove for the security of their marriage. Breakdown "followed closely on a bereavement or suddenly-

developing serious illness in a close relative or friend, illness in or acute danger to the patient himself . . . or a severance of family ties or acute domestic stress, which often constituted a threat to marriage." There had thus been a real or symbolic threat to health or security in a certain type of security-seeking individual. In a proportion of the women in Roth's series the illness had followed childbirth.

Provided that the clinical assessment is made critically in terms of symptomatology, pre-morbid personality and precipitating events, the concept of the phobic anxiety-depersonalization syndrome seems useful as it does carry certain therapeutic and prognostic implications. Roth(2) found electroshock to be contraindicated. In the writer's experience the condition tends to run a remitting-relapsing course in relation to the patient's life situation, but florid or permanent psychosis does not ensue. Some of these cases are probably diagnosed as depressive illness; others as schizophrenia, or pseudo-neurotic schizophrenia(1). However Roth (2) feels that pseudo-schizophrenic neurosis would be a more appropriate title and the natural history of the illness usually bears this out.

A 27-year-old English-born married woman presented symptoms of tension, phobic anxiety, depersonalization, insomnia, labile depression, hypnagogic hallucinations, *etc.* The illness had developed after the birth of her 3-year-old daughter and had improved after some months; only to relapse following her husband's admission to a T.B. sanatorium.

Her childhood had been unhappy. She was the oldest of 6 and had always been shy, timid and anxious as a girl. Her father was a sailor whose rare visits home were among her happiest memories. When she was 11 he finally left the family and some years later died of tuberculosis. After his departure the mother's drinking and promiscuity became even more marked. Mother would disappear from the home for days leaving the patient, at the age of 12, to fend for her 5 younger siblings. This

¹ Hon. Assistant Psychiatrist, Royal Perth Hospital, Perth, Western Aust.

was during the war-time bombing of England and she remembers nights of terror trying to pacify the younger children. Eventually the children were taken into the care of the local authority and at the age of 14 she was sent to Australia under a child migration scheme.

At the age of 17 she was found to have tuberculosis and spent over a year in a sanatorium where she met her future husband. He was 9 years older and of Polish descent. She married some months later "to get away from the hostel." Sexual adjustment is poor but she insists that the marriage is very satisfactory. There are 3 children.

Before her present illness she rarely consulted a doctor (except for her chest condition), was cheerful, energetic and a competent housewife. She was meticulous in her activities and somewhat obsessional (compulsions to hang her wash on the line strictly according to size of garment, to check taps on leaving the house, *etc.*). She had few social contacts outside the family. She was subject to some degree of tension and depression during the premenstrual week.

When first seen she complained of feelings of strangeness—"Not me; lightheaded; as though I were standing behind watching things going on." These feelings were worse in company and later she developed intense and frightening periods of depersonalization lasting 1 or 2 hours and usually occurring in the mornings. She also had episodes of tension and anxiety; mounting on occasions to panic. She was afraid to leave the house alone, to travel on buses; was afraid she might harm the children, lose her senses in company or go out of her mind. She was subject to depressions when she would weep for no reason and become despondent but these were usually short-lived. Her obsessional traits had become more marked. At night she was unable to go to sleep for some time but did not wake early in the morning. As she was going to sleep she would become vividly hallucinated, hearing the voices of her children calling, her neighbours talking, *etc.* She also had *déjà vu* experiences and other perceptual disturbances. On occasions objects and people would appear distorted or changed and scenes or people's faces would seem unfamiliar and terrifying. There was no evidence of any epileptic phenomena.

Psychological testing² disclosed average intelligence and an "overall test pattern pointing

to an immature, dependent, unreflective hysterical character structure. Anxiety and phobic fearfulness are associated. Many of her Rorschach associations and T.A.T. themes centered on early emotional deprivation, with feelings of loneliness, inadequacy and threat of external danger throughout. Considerable resentment over unsatisfied dependency needs exists, with any expression or awareness of this causing guilt and fear of hostile retaliation . . . rejection of the last child as a usurper of her own dependency needs."

The patient was seen regularly at the outpatient clinic and at first improved considerably but after 10 weeks her symptoms were again so intense that she had to be admitted to hospital. After an initial reluctance to stay she settled well into the ward, where her behaviour was conforming but rather exhibitionistic and subtly attention-seeking. In therapy she was at first flirtatious, talkative and demanding, but later was able to discuss her dependency-needs and her pattern of adjustment. Her symptoms again receded and her discharge from hospital was arranged but, because of a minor domestic problem (and also because a problem case conference had been arranged) this was postponed. This decision was unfortunate and thereafter she became so dependent on the hospital milieu that final discharge was only feasible after her husband's return home from the sanatorium. She continues in outpatient therapy and is much improved but by no means symptom-free.

COMMENT

The patient described exemplifies the phobic anxiety-depersonalization syndrome described by Professor Roth (2). She was an immature, dependent, security-seeking person whose first breakdown occurred after the birth of her third child. Acute relapse followed her husband's re-admission to hospital with tuberculosis, when she was left alone at home to cope with her 3 children; circumstances which re-activated adolescent trauma.

In spite of the intensity of her symptoms and the occurrence of nocturnal hallucinations, *etc.*, the illness ran an essentially neurotic course.

ELECTROCONVULSIVE THERAPY FOLLOWING AN OPERATION FOR COARCTATION OF THE AORTA

SHIRLEY RUBERT, M.D.¹

With the development of surgical techniques to correct certain congenital malformations of the heart and great vessels, new questions have been posed, a crucial one being: Can electroconvulsive therapy be used with safety to treat postoperative psychoses?

Case Report: Seven days following a surgically successful repair of a congenital coarctation of the aorta using a synthetic graft, psychiatric consultation was requested. The previous evening, the patient, a 28-year-old, married, television repair man, had become severely agitated and had slept little. He was becoming progressively more exhausted because of hyperactivity. He described a religious experience which he maintained proved he was saved and that his mission was to lead others to salvation. He literally shouted that he felt wonderful and had no worries.

Until a few months prior to his operation the patient lived with the belief that he suffered from severe rheumatic heart disease and hypertension; therefore, his activities had been so restricted that he did not graduate from high school until he was 21. He always felt excluded from group activities other than those at church. He was rejected by the Armed Forces and could not find employment in industry because of his hypertension. As he grew up he worried about possible blindness because of hypertension and feared mental illness because his father had once been in a psychiatric hospital.

At 25, in spite of his family's disapproval, he married the first woman he ever dated. It was when he and his wife were examined because of her repeated spontaneous abortions that the nature of his disability was first diagnosed as coarctation of the aorta. Initially he was unwilling to consult with a cardiologist and cardiac surgeon, but he did so at his wife's insistence. An operation was recommended but a delay of several months ensued while State Rehabilitation Funds were obtained to cover operative expenses. During this period he spoke incessantly about the forthcoming operation and

wondered why the correct diagnosis had not been made earlier.

In the immediate postoperative period, and before the acute psychotic episode, he felt very depressed. He was certain that he was about to die and believed that his family and the doctors and nurses expected this outcome. He had witnessed the death of a younger patient who had undergone a cardiac operation, and he believed that another patient on the service had also succumbed. He knew that his blood pressure had not returned to normal levels, and he feared complications because he was febrile and on antibiotics. The postoperative treatment, especially endotracheal suctioning, was more painful than had been anticipated.

On the seventh day, psychiatric consultation was requested. Intramuscular thorazine (100 mg.) followed by intravenous amylal (approximately 300 mg.) to induce sleep did not result in a sustained change in his state.

The following day he was transferred to the Syracuse Psychiatric Hospital. There, his course was characterized by marked variability. He was almost constantly drenched with perspiration. Periods of muteness alternated with periods of marked agitation and shouting. He became quiet only when he was attended constantly by hospital personnel. His speech became progressively more slurred. This he attributed to an injury to his tongue caused by endotracheal suction. During periods of excitement his blood pressure reached 280/140 but could be lowered to 140/90 with intravenous amylal (250 mg.). There was an intermittent supraventricular tachycardia of 150 per minute. He continually climbed or rolled out of bed and slept on the floor. At times he would collapse in the hallways and lie on the floor. His appearance was that of a person more dead than alive since he was always extremely pale and perspiring and kept his eyes half-closed and his mouth half-open. Eventually every effort at verbal communication completely failed. Thorazine no longer produced alterations in his behavior. His physical condition was deteriorating in that he was losing weight and was failing to maintain an adequate fluid intake.

With the surgical consultant's approval, the decision was made to use electroconvulsive therapy as a life-saving measure. Accordingly, 47 days after his operation, the first treatment

¹ Instructor, Department of Psychiatry, State University of New York Upstate Medical Center and Supervising Psychiatrist, Syracuse Psychiatric Hospital.

was given. No muscle relaxants were used. Marked temporary improvement followed and was sustained after the second ECT. He received 7 treatments. There were no complications. He reverted to his previous personality and he became eager to resume "business as usual." He returned home 13 days following the last ECT.

SUMMARY

Improvement in and more widespread use of corrective surgical procedures for congenital anomalies will result in a new life experience for many patients. It will also in-

crease the life span for some of them. These patients may present new problems for the psychiatrist. In the case reported here, unmodified electroconvulsive therapy was used without untoward effects in a man who had undergone a major intrathoracic vascular surgical procedure involving the use of a synthetic graft. The first treatment was given 47 days following the operation. Certain dramatic aspects of the preoperative and postoperative reactions have also been described.

SIX MONTHS OBSERVATION OF PSYCHOTIC IDENTICAL TWINS¹

DAVID W. SWANSON, M.D.²

Uniovular twins are one of nature's more tantalizing offerings to medical observation. Identical genetic structures are obliged to react with an environment that exerts its random effects on each individual, from the first cellular division until the last. The degree to which the chromosome and the environs contribute to the result remains fertile with discord. A valuable opportunity is offered when identical twins appear, simultaneously, for psychiatric hospitalization. In this instance both patients were observed for 6 months. The following is a report of concordant and discordant behavior in twins and some of the more obvious causes for their differing.

Birth to Adulthood: These male twins were the product of a full term, uncomplicated pregnancy and were delivered at home. Twin A arrived first, as a breech presentation weighing 4½ pounds. Twin B followed immediately as a cephalic presentation weighing 6½ pounds. Physicians hospitalized the smaller infant for observation and his brother was delegated to keep him company, which he did for 3½ weeks. For a portion of this time it was necessary that Twin A be in an incubator. Both were breast-fed for 4 months and bottle-fed until 1 year.

They were toilet trained and able to walk at just over 1 year.

Twin A became a feeding problem and when forced to eat foods he disliked would vomit violently. He began talking at 2 years, several months after Twin B, and demonstrated fear, anger and happiness with much less restraint. Early the two would isolate themselves from other family members, with Twin B appearing calm and protective of his brother.

The twins began nursery school at age 4. Twin A was always inferior in schoolwork and failed the second grade. To avoid separation he attended summer school. In school neither twin made friends. They were aloof, passive and created few problems before terminating their education just prior to graduation. During these years Twin A experienced an enlarged testicle (age 2), St. Vitus Dance (age 10), stuttering (age 10) and severe acne (age 15); all of which Twin B escaped.

Adulthood: Both twins were felt to become more seclusive following adolescence. They would date only on a "double date" basis and bragged of patronizing houses of prostitution. They began smoking and drinking. Later Twin A drank to excess and when intoxicated was violent, pretending he was "Al Capone."

Twin A was rejected for military service, the exact reason being unknown. Twin B was drafted into the navy, but this career aborted at 8 weeks when he was given a "general discharge" because of inability to adjust. Except for this separation they always worked together.

During the year preceding admission to hospital they became more inseparable and

¹ We gratefully acknowledge the assistance of Doctors Borelli and Bielkus, in accumulating this information.

² Illinois State Psychiatric Institute, Northwestern University Service.

would neither eat nor converse with the family. Their belligerence made it impossible for the father to employ them and 2 months before admission they physically attacked him. They would not leave their room, were untidy, dressed bizarrely and felt others considered themselves superior. Although the family considered Twin A as the more disturbed they had them committed together.

Family History: Neither parent had experienced any significant medical or psychiatric illness and there was no family history of such. The father was from a financially deprived background and had worked exceedingly hard to gain ownership of his home and business. He was felt to be aggressive, dictatorial and at times depreciating.

The mother seemed quite passive and fearful. She was generally submissive to her husband and did not protect the children against his dominance. However, when he was absent she would contradict him by making special concessions to the children. There were 2 younger female siblings whose adjustment was felt to be good.

Findings Upon Admission: Twin A was suspicious, possibly hallucinating and irritable. He admitted a "nervous breakdown" due to overwork, and the fear that he might have syphilis which could eat his body away. He berated both parents. Twin B was guarded, angry and kept showing his commitment papers to the physician. He referred to his father having him "thrown in the hospital without reason."

Psychological evaluation resulted in both twins relating intensely to the female examiner, A as sexually provocative and B as physically threatening. They were both unshaven, belched frequently and drew pictures of the examiner. Verbalizations to the same stimuli were many times identical. Twin B appeared more intelligent, but neither cooperated enough to make a complete intellectual evaluation. Point to point correspondence between Rorschach responses did not exist, but both gave obvious evidence of immense hostility toward female figures and considerable anxiety. Twin B demonstrated a paranoid preoccupation with being watched.

Physical examination revealed men who were quite similar in general appearance, mannerisms and height. Twin A weighed 10 pounds more than Twin B and they could be differentiated readily. Ultimately the objective basis for uniovularity was 8 identical blood factors. The electroencephalographic records showed the same regularity and frequency of alpha rhythm. However, the alpha rhythm of B was of lesser amplitude, had a better reactivity

and was driven by photic stimulation.

Hospital Course: During the 6 months of hospitalization Twin A gained 12 pounds and Twin B lost 8 pounds. They were on different wards after 4 weeks and Twin A was on phenothiazines throughout, his brother received no medication. To their respective male therapists they demonstrated little motivation. Twin A was untruthful, sarcastic, drank on passes, expressed peculiar ideas and did not show anxiety until transfer to another hospital was imminent. Twin B originally belligerent and hostile became more withdrawn, silent and suspected people were watching him. He passively accepted arrangements for discharge to parental custody.

Nursing staff observed that the twins spent much time together, apparently without talking. They generally resented all approaches of personnel and pestered the female patients. Twin A was accused of sexual activity with a female patient and physically attacked a male attendant. Both were clever in obtaining alcohol and arranging meetings with each other, even when attempts were made to prevent this contact for therapeutic reasons. Twin A expressed his feelings more readily, got intoxicated and could be sociable, but Twin B remained aloof and withdrew from the nursing staff.

In activity therapy the twins worked on projects irregularly, were slow and lacked skill or creativity. They frequently used this facility as a meeting place.

DISCUSSION

Four observations recur in the case records and merit attempts at explanation: 1. The twins were generally similar; 2. Both were functioning pathologically; 3. A powerful relationship existed between them; 4. They demonstrated dissimilarities.

Numerous similarities in physical findings, behavior and psychopathology were present in these twins. Features frequently concordant in identical twins have been thoroughly discussed from a genetic viewpoint (1, 2, 3, 4). Conclusions from these extensive studies indicate that basic personality make-up is largely determined by heredity, and that adaptive failure follows a course primarily genetically determined.

However, whether due to inborn demands of the twins or inadequacies of the environment, no warm human relationships were successfully established beyond each other. They withdrew at an early age, maintaining an indifferent relation to a world that did

not demand much of them. With adulthood and increasing requirements by family and society they became unable to control their world by indifference, aloofness and evasiveness. In handling these demands they manifested increasing hostility, projection, alcoholic excesses and seclusiveness unacceptable to the family.

In the hospital the relationship between the twins was unique. They preferred each other's constant company and resisted efforts at separation by meeting each other in hallways, activity facilities and their rooms. Actually, when together they conversed very little but gave the impression they were communicating and more at ease than when separated. When confronted together they reacted as a unit. When separated, individual differences became obvious.

This relationship is hardly surprising. It was at birth that the environment made itself clear that these twins were to be viewed as one organism, by subjecting Twin B to unnecessary hospitalization. This is further illustrated by: standardizing feeding schedules and toilet training; assuring that they were together in school; having the same plans for each of them; and finally simultaneous commitment. Independent adaptation was apparently difficult, or at least they were successful in avoiding it.

Despite the above there were obvious dissimilarities. Twin A had more physical difficulties and deficiencies. These were: lower birth weight, slower development, less

intelligence, a greater number of physical incapacities and a pathological reaction to alcohol. Less certainly due to biological difference were early feeding problems, greater impulsivity and more bizarre mental symptomatology. His greater capacity for expressing feelings and socializing may have been the result of increased attention in response to his demands as an infant and child (feeding problem, fearfulness and rheumatic fever).

The dissimilarities influenced discharge planning. The family and society were more willing to tolerate the withdrawn, seclusive, hostile Twin B. Though his adjustment was quite pathological it was more acceptable than the unpredictable behavior of Twin A who reacted with physical aggression and marked loss of control when drinking.

SUMMARY

This is a case report of identical twins observed for 6 months in a hospital setting. Their past history and clinical course are reviewed. Similarities and dissimilarities are described.

SEVERE PAPILLEDEMA ASSOCIATED WITH DRUG THERAPY

ARNOLD G. BLUMBERG, M.D., AND DONALD F. KLEIN, M.D.¹

We have recently observed a patient who evidenced marked ophthalmologic and neurological changes while on drug therapy. Visual disturbances and changes in the ocular fundi have been previously reported with the use of thioridazine (3, 4, 5) and with the experimental phenothiazine NP 207 (2). Patients have reported blurring of

vision and difficulty in light adaptation. The fundi generally showed increase in retinal pigmentation, with retinal edema and hyperemia of the discs. Davidoff (1) has summarized a group of 29 neurological patients who presented with headache and papilledema and who apparently had benign intracranial hypertension of unknown etiology which he termed "pseudo tumor cerebri." The similarity of this group with our patient merits consideration.

¹Depts. of Medicine and Experimental Psychiatry, Hillside Hospital, Glen Oaks, N. Y., and Dept. of Medicine, Long Island Jewish Hospital, New Hyde Park, N. Y.

Case Report: The patient was a 21-year-old Negro girl admitted to Hillside Hospital on Jan. 20, 1960, following repeated hospitalizations for mental disorder. Prior to admission she had received chlorpromazine without complication. She was referred for drug therapy because of a paranoid and depressed state. She received imipramine, beginning Mar. 30, 1960; starting at a dose of 75 mg. daily. This was increased by 75 mg. at weekly intervals to 300 mg. daily, and maintained to May 6. At this time she was agitated and complained of severe headache for the previous 3 days. On admission an electroencephalogram had shown a symmetric, non-focal record with some theta but no delta activity. On May 5, this was repeated and it showed no significant changes from the pre-treatment record.

Because of her agitation, thioridazine, 100 mg. b.i.d., was started on May 7, and imipramine was reduced to 150 mg. o.d. On May 11 the patient reported a stiff neck. The next day thioridazine was increased to 600 mg. daily. On May 13 she reported diplopia and blurred vision without weakness of extrinsic ocular muscles. With increasing symptoms of visual difficulty, 4 days later thioridazine was discontinued and chlorpromazine 400 mg. o.d. was started. Her symptoms became more intense and she complained of persistent diplopia, headache and thickening of her speech. On May 20 examination of her ocular fundi showed severe bilateral papilledema with hemorrhages and edema of the retina. All other cranial nerve function was intact. There were no sensory abnormalities. There were no pyramidal tract signs elicited.

All medication was stopped. A spinal tap on May 24 showed an opening pressure of 320 mm. and closing pressure of 150 mm. with open flow. The protein was 56 mg.%, chlorides 121 mg.%, glucose 72 mg.% and there were 237 fresh RBC's in the fluid. The cerebrospinal fluid and blood serological test for syphilis were both negative. X-rays of the skull were normal except for calcification of the petroclinoid ligament. An EEG May 26 showed mild focal dysfunction manifest by a small amount of delta (4-6 cps) of low voltage in bursts on the right side chiefly posteriorly and occasionally on the left side. This was not changed by hyperventilation. A pneumoencephalogram showed the ventricular system to be moderately and diffusely enlarged within the upper limits of normal and there was no displacement of the ventricles. Analysis of the fluid removed revealed a protein of 22 mg.% and no cells. Twenty-four hours following intra-

venous administration of 300 microcuries of radioactive iodinated serum albumin the skull was scanned for evidence of abnormal foci of radioactivity and no foci were found. Venous oxygen saturation was 95.4% which is consistent with cerebral edema.

The patient improved steadily over the next 2 months so that on July 6 the discs were observed to be flat and no new hemorrhages were seen. On September 16 her visual acuity was 20/300 in right eye and 20/30 in the left eye. There was macular degeneration of the right eye and a central scotoma in the left eye which could be accounted for by localized retinal scarring. There was no significant alteration in pigmentation in either ocular fundus.

DISCUSSION

In pseudo-tumor cerebri, after infection and trauma are excluded, there remains a group whose etiology is undetermined. Employing the criteria of increased intracranial pressure, papilledema, normal spinal fluid protein and cells, normal pneumoencephalogram and recovery, this patient fits the classification of pseudo-tumor cerebri. The electroencephalographic changes noted in this case are more abnormal than those reported by Davidoff.

The ophthalmological response was considerably more cataclysmic than has previously been noted with drug therapy and may represent a more severe degree of retinal edema and hyperemia noted elsewhere (3, 4, 5). The retina is an integral part of the central nervous system, and thus offers a useful locus for the observation of changes induced by drugs affecting the CNS. Whether the clinical picture presented does represent a drug reaction, and whether this reaction was referable to either thioridazine or imipramine cannot be proven in this single case. It would be of importance to look for other cases of ophthalmological reactions to the psychotropic agents and to investigate patients presenting with pseudo-tumor cerebri for a history of drug ingestion.

EXTREME EOSINOPHILIA DURING IMPRAMINE THERAPY

R. J. JOYNT, M.D., AND J. CLANCY, M.D.¹

The effectiveness of imipramine (Tofranil) as an anti-depressant agent is now established. Side effects are well documented and may be expected in a proportion of treated cases. Investigators(1,2) have reported white count elevations during treatment ranging from a mild transient leucocytosis to a total white count in excess of 20,000. Hippus(3) has observed a significant increase of eosinophils, though not in excess of 5%, which is followed by a decrease as treatment is continued. We wish to report an unusual eosinophilic reaction with imipramine during the course of treatment of a depressed patient.

A white woman, aged 50, was first examined at the University Hospital on November 9, 1960. Her chief complaint was inability to sleep for the past 4 or 5 years. In addition, she had a poor appetite, was about 14 pounds under weight, and stated that she was extremely tense. Her husband noted that she was very irritable and had gradually withdrawn from her usual social contacts. There had been occasional episodes of tearfulness. In an effort to deal with her symptoms, she had relied heavily on various tranquilizers, sedatives, and alcohol. Her general physical and neurological examination was not unusual except for tremulousness of the hands. The urinalysis was normal. Blood examination: Hb. = 14 grams, W.B.C. = 10,000, polymorphonuclear leucocytes = 54, lymphocytes = 45, and monocytes = 1. Skull and chest X-rays were normal. An EEG was interpreted as showing abnormal fast activity probably due to excessive medication.

Psychiatric consultation was obtained, and a diagnosis of involutional depressive reaction was made. The patient was placed on imipramine (Tofranil) 150 mg. daily, with small doses of sodium amytal if needed. In her sec-

ond visit, 2 weeks later, the patient was much improved and the dosage of imipramine was reduced to 100 mg. daily. The W.B.C. was 9,400. She was seen again December 16, 1960, and was judged so improved that further reduction in the medication could be made. That evening she noted some stiffness of the neck but was able to sleep. The next morning she could not bend her neck, had a severe generalized headache, and was nauseated. She was admitted to the University Hospital later in the day. Her only findings on admission were a rigid neck and excessive perspiration. Her temperature was 99.2, pulse 64, and blood pressure 140/85. Urinalysis was normal. Blood examination: Hb. = 14 grams, W.B.C. = 30,000, polymorphonuclear leucocytes = 21%, lymphocytes = 18%, and eosinophiles = 61%. Because of the stiff neck and elevated W.B.C. a lumbar puncture was done. The pressure was normal, there were no cells, the Pandy reaction was negative, protein = 40 mg.%, and sugar 52 mg.%. A chest X-ray was normal. Her medications were discontinued. She remained afebrile, and within 2 days felt much better and her neck was supple. Repeat examination of the blood 2 days after her admission showed a drop of the W.B.C. to 26,350 and of the eosinophiles to 31%. A bone marrow examination showed a marked eosinophilia of approximately 50-60% of the cellular elements. No immature cells of the myelocyte series were noted. Trichinella skin test was negative, and there was nothing in her history to suggest a parasitic or helminthic infestation. The blood lupus erythematosus preparation was negative.

She continued to improve, and was dismissed 4 days after her admission. The W.B.C. at that time was 15,450 with 32% eosinophiles. Eight days later in an outpatient examination, the W.B.C. was 7,100 with 10% eosinophiles, 62% polymorphonuclear leucocytes, 1% basophiles, and 27% lymphocytes. Twenty-one days after discharge from the hospital, the W.B.C. was 11,150 with 3% eosinophiles, 65% polymorphonuclear leucocytes, 28% lymphocytes, and 4% monocytes. The red blood count was

¹ Respectively, Assistant Professor of Neurology, and Assistant Professor of Psychiatry, University of Iowa.

4,490,000 and the Hb. was 13.6 grams. She had not been on any medication for this period of time except for some chloral hydrate capsules for sleeplessness. The symptoms of depression were starting to recur.

DISCUSSION

The eosinophilia in this patient was remarkable in its severity and prompt disappearance after discontinuing drug therapy. While very slight elevation of the eosinophils has been reported with imipramine, such a startling alteration in the blood elements has not, to our knowledge, been observed. An attempt was made in this patient to rule out the common causes of

eosinophilia. However, the rapid return of the bloods elements to their normal values after discontinuing drugs served as the best means of differential diagnosis from other causes of eosinophilia such as Loeffler's pneumonia, eosinophilic leukemia, parasitic infestation, and collagen vascular disease.

LOSS OF EJACULATION DURING MELLARIL TREATMENT

FRITZ A. FREYHAN, M.D.¹

This report concerns 3 patients who experienced loss of ejaculation during Mellaril treatment. Such an effect had, to the best of my knowledge, not been encountered or reported in connection with any other phenothiazine compound.

Case 1. A 45-year-old engineer, twice divorced, was referred to me by the company physician because he had manifested personality problems which interfered with his effectiveness as an employee. The clinical examination revealed him to be very tense, suspicious and fearful. Because he had divorced his second wife against the dogma of her church, he felt persecuted by spies sent to this country by the Vatican. Although very reserved and mistrustful he began to relate well in therapeutic sessions. Thorazine was prescribed to attenuate the paranoid tension and to control his hostile outbursts which endangered his position. After several weeks he suddenly discontinued treatment, complaining to his family physician that the Thorazine had seriously disturbed his mental capacities. Since he had shown improvement during treatment but became worse after termination, his company insisted that he continue treatment or leave his job. He returned to my office and complained of very severe and disabling insomnia and demanded medication. In view of his antagonism to Thorazine, I pre-

scribed Mellaril, 100 mg. in the afternoon and at bed time daily. This patient's love life consisted of weekly visits to the same prostitute whom he had favored for several months. On the occasion of his first intercourse with her after taking Mellaril, he reached orgasm but had no ejaculation. He became very upset when he saw me again, felt sure that this was a drug effect and accused me of depriving him of his manhood. I interpreted his complaint as a psychological maneuver and assured him that this had nothing to do with his medication.

Case 2. A 40-year-old married man consulted me because of lack of energy, depressive moods and fears of impotency. Being married the second time, he was father of 4 children. Although he worked every day and was, in fact, quite compulsive about the performance of his duties, he complained of marked tiredness and apathy throughout his working hours followed by anxiety and restlessness in the late afternoon and evening. Clinical examination revealed evidence of a mild depression. I prescribed Dexamy, 5 mg. in the morning and at noon and Mellaril, 50-75 mg. in the early afternoon and evening. When he visited my office a week later, he complained of absence of ejaculation. Although he had experienced difficulties with erection in the past, intercourse had always been normal once he had been able to insert his erect penis into the vagina. He was therefore puzzled about the missing ejaculation and he attributed this to the medication.

¹ National Institute of Mental Health and Saint Elizabeths Hospital, Washington 20, D. C.

Case 3. This 36-year-old married patient was referred by his attorney because of a trial in which he was charged with repeated sexual relations with one of his daughters. His wife complained that he had always been "over-sexed." On the advice of the court, wife and children left him for a probational period during which he was ordered to seek psychiatric treatment. Personality study revealed him to be an aggressive and impulsive individual who had never been able to tolerate sexual frustration. Although he had a good work record, his family and social relations had suffered by his explosive and demanding behavior. He began treatment in a mood of anger, resistance and hostility. Mellaril, 100 mg. t.i.d. was prescribed to help him to regain self-control. Since he wanted to remain faithful to his wife in the hope of a later reconciliation, he satisfied his strong sexual desires by masturbation. Within a week of taking Mellaril he not only observed a lessening of sexual desire but commented that he had "no secretion" when reaching a climax by masturbation. He wondered whether this had been an intended part of the treatment.

The 3 cases are represented in the chronological order of their occurrence. In the first instance, I was misled by strongly suggestive psychological evidence to ignore the somatic implications of the complaint.

When the second patient, so utterly different with regards to personality and psychopathology, reported the same disturbance, I gave serious consideration to the evidence of a Mellaril effect. While I had not abandoned all remnants of doubt about the possibility of coincidence, the third case confirmed the existence of a drug-induced functional disorder beyond reasonable doubt. Discontinuation of Mellaril, moreover, promptly restored normal ejaculation in each patient. The occurrence in 3 patients represents a rather high frequency in the small group of private patients whom I have treated with Mellaril. Thus far I know of only one other case reported in the literature.² It would seem unlikely to get complaints about sexual disfunction from hospitalized patients. But this report may alert physicians to investigate further incidences in office or clinic patients.

While an explanation of the underlying mechanisms of the absence of external ejaculation may come from the urologists, there remains the interesting fact of unique differences which characterize the otherwise similar action spectra of phenothiazine compounds.

² Singh, H. : *Am. J. Psychiat.*, 117 : 1040, May 1961.

INHIBITION OF EJACULATION AS A SIDE-EFFECT OF MELLARIL

MICHAEL GREEN, M.D.¹

I would like to comment on the clinical report by Dr. Singh (volume 117, page 1041, of the *Journal*), "A Case of Inhibition of Ejaculation as a Side-Effect of Mellaril," to provide an explanation of the probable mechanism of this side-effect.

In the January, 1954 issue of *The Connecticut State Medical Journal*, Dr. Sidney Berman and I reported on the "Failure of Ejaculation Produced by Dibenzylamine," a side-effect clearly produced by that drug in 4 of a series of patients to whom it was administered experimentally to observe its effects on the symptoms of various anxiety syndromes. The clue to the mode of action of this potent adrenolytic agent in produ-

ing the side-effect was provided by reports in the neuro-surgical literature of the same phenomenon occurring in some cases following bilateral thoracolumbar sympathectomy. The explanation of this untoward effect is seen as based on the complex physiology of ejaculation which may be summarized as follows : while the striated muscles of the penis are under control of the spinal nerves and, therefore, would remain unaffected by sympatholytic agents, the peristalsis of the vasa deferentia, seminal vesicles, and ejaculatory ducts which discharge semen into the urethra is induced by efferent impulses from the hypogastric plexuses which derive from the thoracolumbar (sympathetic) outflow. A potent sym-

¹ 83 Maple St., Springfield, Mass.

patholytic agent would produce failure of ejaculation by blocking these adrenergic impulses at the neuro-effector junction. Since the phenothiazine compounds all include, among their pharmacological effects,

a greater or lesser degree of adrenergic blockade, it may be assumed that Mellaril, one of this group, produced the side-effect in question by way of the mechanism described.

ANOTHER CASE OF INHIBITION OF EJACULATION AS A SIDE EFFECT OF MELLARIL

JOSEPH HELLER, M.D.¹

A 40-year-old white male patient, schizophrenic reaction, paranoid type, has been in group therapy for one year. At first he was extremely rigid and unable to relate any feelings. During the past 2 months, however, he began to verbalize intense feelings of bitterness and anger. He declared that at times his rage reaches such propelling force that he shouts out loudly when alone. He was afraid of being unable to control this anger and that it might lead to conflict with others. He was, therefore, placed on Mellaril, 25 mg. t.i.d. After having taken this medication for one week he reported feeling much more relaxed and less bothered by his anger, although still aware of its seething quality. He did complain about excessive drowsiness. The dosage, consequently, was de-

creased to 10 mg. t.i.d. The following week he stated that his drowsiness had passed, but mentioned another side effect which he had originally estimated to be unconnected with the drug intake. Three days after the start of his medication, he noticed that his ejaculatory powers were gone although there was no decrease in his sex desires. He had "the sensations and the climax but ejaculation was lacking." Nevertheless, even without ejaculation he felt more relaxed. Patient was advised to discontinue Mellaril for one week, but because of the good relaxing effects he disobeyed this order. Inability to ejaculate persisted. He was again urged to discontinue Mellaril and meproamate was substituted. The following week he reported that after 2 days his ejaculation had returned and remained active. Another attempt was made with Mellaril resulting in a repetition of original events.

HISTORICAL NOTES

BENJAMIN RUSH'S SON

FRANKLIN S. KLAF, M.D.¹

Benjamin Rush, patron saint of the American Psychiatric Association, had a son whose psychiatric contributions have received unjustifiably limited notice. In historical surveys of American Psychiatry(1, 3) James Rush is not mentioned. Wells(8) notes that his main book is not even in the Library of Congress.

James Rush (1786-1869) was the second of 13 children born to Benjamin and Julia Rush. From 1805-1809 he was a medical apprentice to his father, also attending the University of Pennsylvania where Benjamin Rush was professor of chemistry. Wishing to follow his father's medical itinerary, in 1809 at age 23, he left for Edinburgh to complete his medical training, returning to Philadelphia in 1811, where he practiced medicine until his death.

In 19th century medicine James Rush was widely known for his work on phonetics, his textbook(7) becoming a standard work and going through 7 editions. A man of wide literary and cultural pursuits(6), his main interest was psychology. He began planning his study "An Analysis of the Human Intellect" at the same time as his illustrious father was writing the book(4) that became a cornerstone of American psychiatry. Gathering data for more than half a century, he finally published his major work(5) in 1865, 4 years before his death.

The iconoclastic spirit that involved Benjamin Rush in revolutionary activity(2) is evident in his son. James Rush was a tempestuous and extremely complex man who had contempt for metaphysics and mediocrity. He was passionately interested in logic, emphasizing that accumulated experience was wasted unless it was systematized. He spoke of the contemporary medical climate as "this age of medical pretensions and professional trifling," and made many

enemies. Influenced in Scotland by Dugold Stewart, he was philosophically 50 years ahead of his time, championing the logic of the pre-Socratics while railing against Aristotelian syllogisms.

Despite these varied interests, James Rush spent his life trying to understand the workings of the mind. Utilizing his background in phonetics, he first sought the understanding of mental phenomena in the interrelationship between speech and thought. By emphasizing the importance of sensation, Rush adhered to the tradition of Locke's "tabula rasa." Human knowledge was derived solely from sensory experience. Rush postulated that thinking arose as a physical function produced by sensory data on the brain. Sensory perceptions determining mental functioning were of 3 types: 1) primary perception; 2) memorial perception; 3) joint perception. Primary perceptions were the first constituents of mental life; the brain perceived outer sensory stimuli in temporal sequence, registering memorial perceptions—the images and universal types that were left behind when "the things which produced the primary perceptions are removed from before the senses." Only when joint perceptions were received could the relationship between individual images and universal types be learned. Joint perceptions were the combined perception of 2 or more primary and/or memorial images.

Rush believed that all mental functioning, in health and disease, could be explained by using this schema. An orderly registering of sensory experience enabled the human being to gain a sense of time and space. Language developed as a series of verbal signs for every primary perception. By imitation, the human voice was able to transmit these verbal signs of primary perception.

Dreams and insanity were explainable in James Rush's conceptual framework. In dreams primary perception did not exist;

¹ Psychiatrist, High Point Hospital, Upper King Street, Port Chester, N. Y.

the dreamer recalled only memorial perceptions. Anticipating Freud by 35 years, Rush equated the perceptual disturbance in insanity with that seen in dreams, stating that in one type of insanity, which he called memorial insanity, dream-like states were perceived as if they were real. Insanity was defined as an inner perceptual disturbance containing no external disturbing elements.

Not content with explaining the mind and its disorders, James Rush next attempted an early form of character analysis. Unfortunately, his hostile temperament got the better of him, and he used the second part of the book to vent many prejudices. Sample headings included explanations "Of the Popular and Conforming Mind of the Physician," and "Of the Contracted Mind of the Priest." The volume ends with an analysis of Shakespeare's character, concluding that Shakespeare's perceptions, like those of all creative geniuses, were involuntary and inexplicable.

Like his father, James Rush was a brilliant rebel, full of prejudices yet blessed with rare imagination and psychological acumen. He

predicted that his books would "lie on the dusty shelf." Unfortunately this proved true, and posterity has not taken notice of his unique talents.

PSYCHOTHERAPY BY RECIPROCAL INHIBITION

MARK A. STEWART, M.R.C.S., L.R.C.P., M.A.¹

In the past decade there has been a growing interest in relating the practice of psychotherapy to the principle derived from experiments on learning. Dollard and Miller's book on *Personality and Psychotherapy* (1), published in 1950, did much to stimulate interest and is something of a classic in this field. Another major contributor has been O. H. Mowrer, who has written extensively on this topic (2). A number of articles, too, have been published in the last few years, recording specific cases or therapeutic techniques (3, 4, 5). These techniques have been drawn from such learning theory concepts as conditioned aversion, desensitization and massed practice.

Reciprocal inhibition, one of these specific techniques, was the subject of a book by

Wolpe published in 1958 (6). The principle that goes by this rather forbidding title is that of extinguishing one response by eliciting another, incompatible response. Wolpe describes the actual use of this principle with a number of patients, chiefly suffering from anxiety reaction, phobic or obsessive-compulsive neurosis, and he reports very impressive results with the technique.

It is interesting to find that our predecessors of a century ago made use of the same psychotherapeutic artifices, though they did not foresee their theoretical significance. A paper (7) presented at the Royal Academy of Medicine in Paris in 1845 describes the treatment of a patient by means of some special manoeuvres, one of which was clearly "reciprocal inhibition."

The author of the paper was F. Leuret, a physician at the Bicêtre, and an ex-pupil of Esquirol. His report concerns the case of

¹ Department of Psychiatry, Washington University School of Medicine, St. Louis, Mo.

Thierry, a 30-year-old wine merchant, admitted to the Bicêtre in 1843 with a 10-year history of obsessional thoughts. These had become so bad that he was no longer able to carry on his business. Leuret describes vividly how he laid down the treatment plan to his intern, M. Marcel, along lines taught him by Esquirol. He and the intern played two contrasting roles with the patient. Leuret was stern and demanding, while the intern was the patient's friend and comforter, and appeared to side with him against Leuret.

Shortly after Thierry's admission, Leuret accused him of being lazy, since he found him lying in bed when he made rounds, and ordered him to find some work to occupy him. Leuret also refused to increase Thierry's ration of food, which apparently upset him considerably. After rounds, the intern went back and advised Thierry to read, and learn songs which he could recite to Leuret the next day, and promised to double his food ration without letting Leuret know. Thierry at first rejected this idea, saying that he could never learn a song because of the interference of his "ideas," but the intern went, leaving the impression that he relied on Thierry to follow his advice.

The next day Thierry had made a fair attempt to do the work, but Leuret acted as though he was unimpressed and demanded that he work much harder. The intern was sympathetic with Thierry, but pointed out that they would both get into trouble if Leuret found that his food ration had been increased and he had not done the work expected of him.

The third day, Leuret was again unimpressed with the amount of reading Thierry had done, and his attempts to recite, and angrily cut the food allowance on finding the intern had increased it. By the following day Thierry had learnt a few lines to recite, and had done quite a bit of reading. Leuret seemed satisfied, and ordered that the food allowance be increased. Thierry was very happy and promised to learn the song he was assigned for the following day. At the next rounds Thierry sang four couplets of the song, but Leuret asked for renewed efforts and for several days after this Leuret acted as though he was far from satisfied and again cut the food allowance.

This regime continued for about 6 weeks, with Thierry's recitals and other work steadily improving, but never quite catching up with Leuret's expectations. Meanwhile, he apparently experienced less and less interference in his

assigned tasks from his obsessional thoughts, and tended less and less to repeat himself in his recitals. At the end of the 6 weeks Leuret asked him about his repetitive ideas and Thierry told him that he had not had them for several days, and that he felt much better. After 2 more weeks in the hospital Thierry was discharged, still greatly improved. Leuret found him work as a nurse to one of his patients, and he reported that a year later Thierry was well and a very successful nurse.

In discussing his method of treatment Leuret confines himself to one very interesting problem, the question of the mentally ill patient's motivation to get well. He points out that the physically ill patient often seeks out instinctively what will relieve his sickness, *e.g.*, the rheumatic patient will rest, while the mental patient tends to do what will make him worse. This raises the question of how the psychiatrist can lead the patient to behavior which will have a salutary, rather than harmful, effect without antagonising or frightening him. Leuret remarks that the physician has to draw on whatever strengths or weaknesses the patient has in order to motivate him to recovery, and he refers specifically to the use of a patient's hunger drive, which he had certainly illustrated in the treatment of Thierry. More generally Leuret comments that the psychiatrist has to be subtle and even devious in bringing patients back to their right mind. I presume that here he is referring to the use of such manoeuvres as the role-playing that he and his intern carried off with such effect in the handling of Thierry.

Leuret does not specifically discuss his technique of blocking the obsessional thoughts of his patient by inducing him to do hard mental work, though, as I have indicated, he was well aware of how the patient's "drive state" had to be manipulated in order to do this. In a general way, this substitution of a healthy activity for pathological behaviour was a guiding principle of the "moral treatment" era, which relied heavily on farmwork, handiwork, edifying lectures and so on, for all classes of patients. But I believe that this report of Dr. Leuret's deserves to be recognised as anticipating our sophisticated psychotherapeutic techniques of today, because he presents a specific tech-

nique to be followed with a specific type of patient, rather than a general method for use with all patients. The resemblance between Leuret's method and that which Wolpe describes in his book *Psychotherapy by Reciprocal Inhibition* is very striking. In fact it would seem that Leuret unwittingly used exactly the same principle, and with the same kind of patient.

COMMENTS

SOVIET PSYCHIATRIC NOMENCLATURE

NATHAN S. KLINE, M.D., F.A.C.P.,¹ MARK G. FIELD, Ph.D., F.A.S.A.,²
AND JASON ARONSON, M.D.³

As cultural contacts between East and West continue to expand, it becomes increasingly important for the two sides to be sure they speak the same scientific language, *i.e.*, that the words and phrases, once they have been translated, mean the same things. It is particularly critical, in making cross-cultural surveys or comparative studies, that we do not compare apples with pears, and make judgments accordingly. The visit of two eminent Soviet psychiatrists⁴ to New York City (who were part of a six man delegation to a Joint Meeting of the Academy of Medical Sciences of the USSR and the New York Academy of Sciences) afforded us a unique opportunity to discuss two papers on Soviet psychiatry (1, 2) we recently had written. We questioned them at some length on problems that we had some doubts about and particularly discussed one question that often proves most baffling in comparative work: that of diagnostic categories or labels. It is generally accepted that this is a problem that plagues us at home when we compare statistics issued by two different authorities, or even two different hospitals. In international contacts and comparative research the problem is compounded by the problem of translation, cultural differences and dissimilar psychiatric and therapeutic orientations. For example, no reports equivalent to *Patients in Mental Institutions* issued by the Department of Health, Education and Welfare, Public Health Service could be found for the Soviet Union. Our queries on the subject brought forth the response that statistics were available "somewhere," but that for reasons our respondents did not presume to understand these were not being made

public by the Ministry of Health USSR, the logical authority to do so. The one table on hospitalized patients in the Soviet Union we had been able to find had been published by Professor Snezhnevskii but was extremely poor and vague since it purported to represent percentages of "hospitalized patients" (1950-1954) and yet did not give: 1. total numbers of patients the figures represented; 2. breakdowns by age; 3. by sex; 4. by area; 5. by admissions, readmissions, discharges and death. While our respondents deplored the lack of better statistical data, they did shed some light on the question of diagnostic categories. Our comparisons had been hampered by the fact that the Soviet sources listed either 17 or 19 such categories as against the more than 30 used in the American standard nomenclature. We were interested in finding out whether the manner in which we had collapsed the U. S. categories into the Soviet ones was essentially correct. It emerged from the conversation that this had been the case except for a few minor points. It was suggested, for example, that our assumption that the American "Birth Trauma" category which we had classified under the Soviet category of "Traumatic Psychoses" would better fit under the Soviet category of "Oligophrenia."

One of the most interesting and unexpected placement of patients was in respect to the group we know as paranoid states or paranoia. Since no such category is used in the Soviet statistics we had surmised that they would be subsumed under schizophrenia.

According to our respondents, however, patients with fixed but limited paranoid delusions who are free of hallucinations and who show no "primary changes" belong under classification 18 (reactive disorders) since this is where, in the Soviet Union, transient paranoid episodes and paranoia are listed. There must be other changes in

Standardization of Soviet and American Psychiatric Diagnosis

SOVIET CATEGORIES *	AMERICAN CATEGORIES * (CODE NO.)
1. Schizophrenia	Schizophrenic reactions (22)
2. Epilepsy	Acute brain syndrome associated with convulsive disorders (05). Chronic brain syndrome associated with convulsive disorders (16).
3. Manic-depressive psychosis	Affective reactions (21).
4. Brain circulatory disturbances or cerebral arteriosclerosis and other circulatory disorders	Acute brain syndrome associated with circulatory disturbances (04). Chronic brain syndrome associated with circulatory disturbance (15).
5. Pre-senile psychoses	Involuntional psychotic reactions (20).
6. Senile psychoses	Chronic brain syndrome associated with disturbances of metabolism, growth or nutrition; with senile brain disease (17.1).
7. Lues or cerebral syphilis	Chronic brain syndrome associated with central nervous system syphilis: Meningovascular (11.1). Other central nervous system syphilis (11.2).
8. Progressive paralysis	Chronic brain syndrome associated with central nervous system syphilis: Meningoencephalitic (11.0).
9. Psychosis with infectious or virus diseases or infectious psychosis	Acute brain syndrome associated with infection (01). Chronic brain syndrome associated with intracranial infection other than syphilis (12).
10. Intoxication psychoses	Acute brain syndrome associated with intoxication: Drug or poison intoxication, except alcohol (02.2). Chronic brain syndrome associated with intoxication: Drug or poison intoxication, except alcohol (13.1).
11. Alcoholic psychosis and chronic alcoholism	Acute brain syndrome associated with intoxication: Alcohol intoxication (02.1). Chronic brain syndrome associated with intoxication: Alcohol intoxication (13.0). Sociopathic personality disturbance: Alcoholism (addiction) (52.3).
12. Narcomania	Sociopathic personality disturbance: Drug addiction (52.4).
13. Mental disorders with diseases of the internal organs	Acute brain syndrome associated with metabolic disturbance (06). Chronic brain syndrome associated with disturbance of metabolism, growth or nutrition; with other disturbance of metabolism, etc., except pre-senile brain disease (17.3)
14. Mental disorders (including neuroses) with brain trauma	Acute brain syndrome associated with trauma (03). Chronic brain syndrome associated with trauma: Brain trauma, gross force (14.1). Following brain operation (14.2). Following electrical brain trauma (14.3). Following irradiational brain trauma (14.4). Following other trauma (14.5).
15. Psychoses with organic trauma	Acute brain syndrome associated with intracranial neoplasm (07). Chronic brain syndrome associated with new growth (18).
16. Oligophrenia (including birth trauma)	Chronic brain syndrome associated with diseases and conditions due to prenatal (constitutional) influence (10). Chronic brain syndrome associated with trauma—Birth trauma (14.0). Mental deficiencies (60-62).
17. Psychopathy (ies)	Sociopathic personality disturbance: Antisocial reaction (52.0). Dy-social reaction (52.1). Sexual deviation (52.2).
18. Neuroses, psychoneuroses and reactive disorders	Paranoid reactions (23). Psychophysiologic autonomic and visceral disorders (30-39). Psychoneurotic disorders (40). Personality pattern disturbance (50). Personality trait disturbance (51). Special symptom reaction (53). Transient situational personality disorders (54).
19. Others: neuropsychiatric, examination cases, and undetermined diseases	Acute brain syndrome with disease of unknown or uncertain cause (08). Acute brain syndrome of unknown cause (09). Chronic brain syndrome associated with disturbance of metabolism, growth or nutrition. Pre-senile brain disease (17.2). Chronic brain syndrome associated with diseases of unknown or uncertain cause; chronic brain syndrome of unknown or unspecified cause (19). Psychotic reaction without clearly defined structural change other than above (24).

* According to Snezhnevskii, "Dispensary Method of Registering Psychiatric Morbidity and the Soviet System of Psychiatric Service," *Living Conditions and Health*, v. 1, No. 4, pp. 236-241, 1959.

* According to American nomenclature(3).

personality beside the paranoid delusion in order to establish a diagnosis of schizophrenia. In the absence of such changes, it is assumed that the paranoid delusions are psychogenic.

In psychiatry more than in any other medical field a direct translation of diagnostic terminology is not completely satisfactory. Translation must be supported by an understanding of the different cultures, political

institutions, medical organizations and social structures of these two industrial societies. In the psychiatric field this understanding can come from an extensive reading of the literature, both medical and non-medical, from direct contacts and interviews between American and Soviet specialists, and from stays of at least 6 months or more in each other's country. Brief contacts, 30-day whirlwind tours, and presentation of papers at international meetings can only serve to begin the personal bridges over which long-term relationships can be established. In any case mankind can only benefit from increased contacts between medical men of East and West, as their concern is always a common one.

The table opposite lists usual Soviet diagnostic categories and corresponding APA categories(3) in parallel columns.

Copies of a table comparing the USPHS and Soviet categories as well as the categories proposed by Kerbikov, Ozeretskii, Popov, and Snezhnevskii in their recent *Textbook of Psychiatry* can be obtained by writing to the authors.

LIFE LINE

Blow on the coal of the heart.
 The candles in churches are out.
 The lights have gone out in the sky.
 Blow on the coal of the heart
 And we'll see by and by . . .

—ARCHIBALD MACLEISH

OFFICIAL REPORT

REPORT OF THE CHAIRMAN OF THE BOARD OF TELLERS

The Board of Tellers of the American Psychiatric Association here presents the successful candidates as determined from counting the recent mail ballot.

For President-elect, Dr. C. H. Hardin Branch of Salt Lake City, Utah.

For Vice-President, Dr. Henry W. Brosin of Pittsburgh, Pennsylvania.

For Vice-President, Dr. Titus Harris of Galveston, Texas.

For Secretary, Dr. Harvey J. Tompkins of New York, New York.

For Treasurer, Dr. Addison M. Duval of Jefferson City, Missouri.

The contest for Councillors was strikingly close. Of the six candidates presented by the Nominating Committee, the five highest scores showed a spread of only 630 out of 5000 votes!

This may well be considered a credit to the Nominating Committee and to the thoughtful voting of our membership.

You have elected for Councillors:

Dr. Alfred Auerbach of San Francisco, California.

Dr. Herbert S. Ripley of Seattle, Washington.

Dr. Cecil Wittson of Omaha, Nebraska.

The statistical report of the Board of Tellers has been filed with the Secretary of the American Psychiatric Association at the central office.

Our President, Dr. Robert H. Felix, on transferring the gavel into the able hands of our incoming President, Dr. Walter E. Barton, becomes a voting member of Council by constitutional provision.

The Board of Tellers is indebted to our Executive Assistant, Mr. Austin Davies, and to his staff of the New York office for their efficient service as Custodian of Ballots and for their generous and gracious cooperation in serving as members of the vote-counting teams.

I should like to express appreciation to each member of our Association who relayed their reactions to the election procedures through comments on ballots, in

letters, or in conversation. These communications enabled the Board to make recommendations based upon the opinions of APA members.

A brief review will remind us of the changes in election procedure within the last 10 years, to adapt to the developing requirements of a rapidly growing organization. Our membership has almost doubled within this decade.

For many decades open poll voting at the Annual Meetings presented an increasing problem. Furthermore, it limited the franchise to those attending the Annual Meeting, a small proportion of the total membership. Constitutional changes provided the mechanism for the first mail ballot in 1952.

The report of the Board of Tellers in those years was rendered at the Annual Meeting on a large blackboard with each name and its numerical count. For obvious reasons, change was indicated. In 1958, constitutional amendments provided that the Board of Tellers should announce the successful candidates only. The complete statistical report of the Board of Tellers with numerical data was to be filed with the Secretary of the Association where it would be available to individual members upon request.

Beginning with 1958, the Chairman of the Board of Tellers, aware of the feeling about election mechanics through comments and personal communications, conducted interviews with American Psychiatric Association members to obtain constructive opinions. Individuals from many geographic areas as well as different classes of membership, and with varying types of experience within the APA were included in the sample. Recommendations based on the information obtained as well as on the awareness of the increasing burden for the Board of Tellers were considered by Council.

In 1960 the Council approved three changes:

1. That the ballots for officers offer the member a choice of unit affirmation of the

panel proposed by the Nominating Committee or the opportunity to vote separately for individual officers.

2. That the Chairman of the Board of Tellers be consulted about the format of the ballot to facilitate counting.

3. That biographic data for nominees be included on the ballot. "The biographic data would consist of : the individual's present position, any APA Committee Chairmanship and elected positions held in the past ; and positions held in the Assembly of District Branches."

This year 55% of the ballots mailed were returned.

Of the voting members, 96% utilized the unit vote for officers.

Only two ballots for councillors indicated that the member felt he had insufficient knowledge upon which to base a decision.

To answer some of the questions frequently raised, the Chairman of the Board of Tellers made a study of the tallies for the past 5 years. This has revealed enough correlation between election and ballot position to warrant further consideration. With respect to contested Councillor elections, the most dramatic finding can be told simply.

No candidate in the number 1 position ever lost ! That is, the candidate first on the ballot (position 1) won consistently in each of the 5 years. Since candidates are arranged alphabetically (according to constitutional provision), a member whose last name begins with a letter near the head of the alphabet gains undue advantage.

The member in position 3 was successful in 4 out of 5 elections.

Does this mean that the candidate at the bottom of the alphabet is also at the bottom of the tally ? No, it doesn't. The candidate listed last on the ballot won 3 out of 5 years. Of these 3 years, only twice did the Nominating Committee offer six candidates (1957 and 1961). The candidates in that position won both times, representing a 100% success for position 6. The nominee in the 5 position won 2 out of 5 years as did the member in the number 2 spot.

There was, however, a hard-luck spot. That was position 4. *No candidate in position 4 ever won an election !*

The 1961 election was no exception. As mentioned above, only 630 votes separated the

top candidate from the next to the bottom one. But, 600 votes separated the latter from the low man who, as usual, was in position 4.

Position 1, 2, and 3, traditionally supposed to be the winning combination, has been so only twice during the past 5 years. In both instances there were five nominees.

Similarly, positions 1, 3 and the last position on the ballot have been winners twice ; in 1957 when there were six nominees and in 1959 when there were five.

The 1st, 5th and 6th candidates listed on the 1961 ballot won (positions 1, 5, & 6)—the only success for this combination of positions.

On May 7, 1961, I presented this report to Council. In view of the apparent advantage of positions 1 and 3, and the disadvantage of position 4, I recommended that the APA abandon the current practice of alphabetical listing of candidates. Council received this recommendation understandingly, and is working on plans for its implementation.

The role of alphabetical position may be shown in another way. Of total APA membership, 64% have names in the A to M bracket, and 36% have names in the last half of the alphabet. If alphabetical position did not play a role, one would expect that our officers and Councillors would show about the same distribution : 64-36.

But 12 of the 15 elected Councillors—that is 80%, belong in the first half of the alphabet. And our present Officer-Councillor leadership shows a 73-27 distribution instead of the theoretically expected 64-36 ratio. Two of the three Councillors making the 20% minority (N-Z) referred to above were elected in 1961.

The fact that all three of 1961's victors were from the West raises the question of geographical distribution.

The new members of Council will effect some shift in the present proportion of 74% from the east and 26% from the west of the Mississippi, among our present officers and members of Council (30 in all).

Four of our current officers and members of Council, or 13%, are from south of the Mason and Dixon line. The remaining 87% includes two from Washington, D. C. and one from Canada.

The distribution of our governing body according to area is :

Area 1—Twelve : six voting and six ex-officio.

Area 2—Four : all voting.

Area 3—Five : two voting and three ex-officio.

Area 4—Five : four voting and one ex-officio.

Area 5—Four : two voting and two ex-officio.

The Board of Tellers welcomes your continued comments, reactions, and suggestions. Such communications from the membership are of value to our elected leaders in obtaining the pulse of our organization and in prescribing wisely and officially for its continued growth and maturity.

Evelyn Parker Ivey, M.D.,
Chairman.

NO—YES

When words are found to be a roundabout way of communication, the Zen master may utter "Katz!" without giving what is ordinarily considered a rational or intelligible reply.

In the same way, when told that he looks like a dog, he will not get excited and make an angry retort. Instead, he may simply cry "Bow-wow," and pass on.

—D. T. SUZUKI

NEWS AND NOTES

NEW MENTAL HEALTH TRAINEESHIP FOR GRADUATE NURSES.—The traineeship program of the National Institute of Mental Health was recently extended to include an undergraduate traineeship for graduates of diploma schools of nursing who are interested in a career in psychiatric-mental health nursing. These traineeships are available in schools participating in the National Mental Health Training Program, and provide an annual stipend of \$1,800 plus such tuition and registration fees as required by the educational institution.

This program continues to provide several levels of traineeship support for nurses seeking specialized graduate preparation in universities offering programs to prepare individuals for expert clinical practice, teaching, administration, consultation and research in colleges and universities, and in hospitals and community and public health agencies. Stipend support is provided for training leading to the master's and doctor's degrees.

For further information write to the Training Specialist in Psychiatric Nursing, Training Branch, National Institute of Mental Health, National Institutes of Health, Bethesda 14, Md.

CANADIAN MENTAL HEALTH ASSOCIATION ANNUAL MEETING.—Growing public interest in the field of mental health was indicated by the impressive attendance at the 43rd annual meeting of the Canadian Mental Health Association, June 1, 1961.

The program was significant in that its total focus was on the Association's scientific research program. Scant attention was paid to the traditional emphases on improving mental hospital care and the volunteer services to the sick. The program attracted a large group of people from the social, industrial and business leadership of Canada. More than 200 attended the public symposium to hear Drs. Omond Solandt, Noël Mailloux o.p., and Patrick McGeer, discuss research in the field of mental health. In the evening at the Association's annual banquet, nearly 350 people heard

Dr. Daniel Blain, director of California's mental hygiene department.

Accepting chairmanship of the board of directors after serving 6 years as national president, J. S. D. Tory, QC, mentioned that a professional survey 4 years ago gave little encouragement of financial support for the unique approach to research proposed by the CMHA. Each year, however, has shown that contributions to the mental health research fund have been growing. It is anticipated now, that this research plan will prove to be successful and important.

Under the CMHA plan, funds are allocated to *persons*, instead of the traditional pattern of granting to *projects*. The amount is large enough to assure income to the recipient for 3 or 4 years and it is paid directly to him. In this period the scientist is totally free to follow whatever leads develop from his research, without having to redefine the work in which he is engaged. Dr. Mailloux, a psychologist, and Dr. McGeer, a psychiatrist and biochemist, were the first beneficiaries of the Fund. Dr. Solandt, a vice-president of Canadian National Railways and formerly director of Canada's Defence Research Board, was director of the Fund in 1960.

Dr. Blain's address reported on the philosophy and growth of community mental health services in California.

Growth of the Canadian Mental Health Association was highlighted in a review by the President of his 6 years of service. From less than 2000 in 1954, the membership had grown to 125,000 in 1960. Income had increased from about \$100,000 in 1954 to \$700,000 in 1960.

The Association's annual report—an 8-page summary designed for ready reading—was presented at the meeting and is now available upon request by writing to the Association at Box 555, Toronto 5.

AMERICAN ACADEMY OF CHILD PSYCHIATRY.—At the recent annual meeting of this Society in Chicago Dr. James M. Cunningham of Dayton, Ohio, was installed as

president and Dr. Reginald S. Lourie, head of psychiatry at Children's Hospital, was named president-elect. Dr. Joseph Weinreb was elected secretary and Dr. Abram Blau, treasurer.

THE MODERN FOUNDERS.—Dr. and Mrs. Francis Gerty were hosts at the annual luncheon meeting on Wednesday during meeting of the APA. The speakers included Doctors Barton, Bond, Lebensohn, Ross, and Mr. O'Mara, the new APA Librarian-Archivist.

New Founders awarded certificates were : Doctors A. Auerback, Ed. Billings, Hardin Branch, Hamilton Ford, Walter Obenauf, John Saunders, and Harry Solomon.

Officers elected for the coming year are : Chairman, Dr. Leo Bartemeier, Vice-Chairman, Mrs. Daniel Blain, and Secretary-Treasurer, Dr. Bob Mearin.

DR. FARQUHARSON TO DIRECT CANADIAN MENTAL HEALTH ASSOCIATION RESEARCH FUND 1961.—Dr. R. F. Farquharson, Professor Emeritus of Medicine, University of Toronto, and chairman of the Medical Research Council of Canada, has accepted the direction of the C.M.H.A. research fund for the coming year. He will select the applicant to receive this annual grant which now amounts to \$25,000.

WESTERN INSTITUTE ON EPILEPSY.—The 13th annual conference of the Western Institute on Epilepsy has been scheduled for October 11 through 14, 1961. These meetings are to be held at the Granada Hotel and Inn at San Antonio, Texas.

The papers will deal with the clinical, biochemical, neurophysiologic, psychological and electroencephalographic aspects of epilepsy.

For information address Frank Risch, Ph.D., Secretary-Treasurer, 3097 Manning Ave., Los Angeles 64, Calif.

AMERICAN PSYCHOSOMATIC SOCIETY.—At the annual meeting of the American Psychosomatic Society April 28-30, 1961, Atlantic City, the following persons took office : President, Stewart Wolf, M.D. ; President-

elect, Julius B. Richmond, M.D. ; Secretary-Treasurer, Eugene Meyer, M.D. ; Elected to Council were, Morton D. Bogdonoff, M.D., Stephen Fleck, M.D., Adrian M. Ostfeld, M.D., Alvin P. Shapiro, M.D.

The 19th annual meeting of the Society will be held March 31-April 1, 1962, in Rochester, N. Y.

KYBERNETIK.—This new Journal, the first issue of which appeared in January, 1961, deals with the "transmission and processing of information and with control processes in both organisms and automata."

It is edited by H. B. Barlow, Cambridge, Eng., M. Halle, W. A. Rosenblith and N. Wiener, Cambridge, Mass., B. Hassenstein, Freiburg i.Br., W. D. Keidel, Erlangen, I. Kohler, Innsbruck, K. Küpfmüller, Darmstadt, H. Mittelstaedt, Seewiesen, Obb, W. Reichardt, Tübingen, J. F. Schouten, Eindhoven, M. Schützenberger, Poitiers, K. Steinbuch, Karlsruhe.

The publisher is Springer-Verlag, Berlin, Göttingen, Heidelberg.

Contributions may be in German or English. Maximum price for 1961: DM 80.

The initial number of *Kybernetik* contains papers on Processing in the Nerve Cell for regulating Voluntary Movements, Letter Constraints within Words in Printed English, Pawlow and his Dog, a Demonstration Model for the "Conditioned Reflex," and four other contributions.

This issue, 56 pp. (9 pp. in English), 72 charts, diagrams, tracings, etc.

ILLINOIS PSYCHIATRIC HOSPITAL.—On March 15, 1961, the following members of the Illinois Psychiatric Society were elected to office for the year 1961-1962 : President, Dr. Melvin Sabshin ; President-Elect, Dr. Lester Rudy ; Secretary-Treasurer, Dr. Harold Visotsky ; Councilors, Dr. Joel S. Handler, Dr. John Adams ; Delegate to American Psychiatric Association Assembly, Dr. Jewett Goldsmith ; Alternate Delegate, Vacant—to be filled in September 1961.

AMERICAN BOARD OF PSYCHIATRY AND NEUROLOGY, INC.—The following examinations are scheduled by the American Board

of Psychiatry and Neurology, Inc. : Oct. 9 and 10, 1961—Chicago, Ill. ; Dec. 11 and 12, 1961—New York, N. Y. ; and April 2 and 3, 1962—San Francisco, Calif. *

VESTERMARK FELLOWSHIPS TO BE CONTINUED.—The Smith Kline & French Foundation has announced an additional grant of \$10,000 for the continuation of the APA's Vestermark Fellowships, under which selected medical students are provided with the opportunity for full time work in public mental hospitals during the summer months. This grant brings the amount awarded by the SK&F Foundation to the APA for various fellowships in psychiatry during the past 6 years to \$200,000.

Applications should be submitted directly to the SK&F Awards Committee at the APA Central Office, 1700 18th Street N.W., Washington 9, D. C.

DR. DIAMOND HEADS MANHATTAN STATE HOSPITAL.—Dr. Oscar K. Diamond was appointed Director of Manhattan State Hospital, Ward's Island, effective May 15, 1961.

Dr. Diamond entered the New York State service in 1946 and served as assistant director at Creedmoor State Hospital for 5 years previous to the present appointment.

A. E. BENNETT NEUROPSYCHIATRIC RESEARCH FOUNDATION AWARD.—At the annual meeting of the Society of Biological Psychiatry in Philadelphia, June 11, 1961, Dr. Larry Stein, a research psychopharmacologist at Wyeth Laboratories, Philadelphia, received the A. E. Bennett award of \$500 for his research report on a possible neurophysiological basis of depression.

Dr. Stein was previously associated with the Walter Reed Army Institute for Research and the VA Laboratories in neuropsychiatry.

NATIONAL ASSOCIATION FOR MENTAL HEALTH.—Under numerous and striking gains in this field during the past decade as noted by the president of N.A.M.H., Mrs. Felix Dupont, Jr., in the annual report of the Association, most striking are :

The estimate that patients entering mental hospitals with diagnoses of schizophrenia, manic-depressive or involutional psychosis now have a 65% possibility of returning to community life within a few months.

Also that greater numbers of psychiatric cases are now treated in community-based centers. More than 950 general hospitals in the United States operate psychiatric units. An increasing number of communities have outpatient clinics for both adults and children as well as aftercare centers for the follow-up of patients discharged from hospitals.

OPEN-STAFF PSYCHIATRIC HOSPITALS.—In June 1962 a meeting will be held at the Institute of the Pennsylvania Hospital when the question of open-staff privileges in psychiatric hospitals similar to those in general hospitals will be considered by psychiatrists assembling from a majority of the states.

Dr. Lauren A. Smith, physician-in-chief of the Institute, commenting on the fact that certain psychiatric hospitals, including the Institute of the Pennsylvania Hospital, have made concessions in the direction of open-staff hospitals, indicates the advantage of permitting not only referring psychiatrists but also the family doctor to collaborate with the staff in patients' treatment.

Dr. Walter E. Barton, president of the APA will lead the panel of speakers.

The Smith Kline and French Laboratories of Philadelphia are to underwrite the cost of the meeting.

THE AMERICAN NEUROLOGICAL ASSOCIATION.—At the 86th annual meeting of this Association held in Atlantic City, N. J. on June 12-14, 1961, total registration was 626. The following officers were elected for the year 1961-62 : President, James L. O'Leary, St. Louis, Mo. ; President-Elect, Charles D. Aring, Cincinnati, Ohio ; 1st Vice-President, Francis L. McNaughton, Montreal, Canada ; 2nd Vice-President, Robert S. Schwab, Boston, Mass. ; Secretary-Treasurer, Melvin D. Yahr, New York, N. Y. ; Assistant Secretary, Clark Millikan, Rochester, Minn. ; Editor of Transactions, Melvin D. Yahr, New York, N. Y.

Dr. Harold Wolff was elected to the Council for 5 years ; Dr. Fred Plum for 2 years. Dr. Charles Rupp was appointed representative to the American Board of Psychiatry and Neurology for 4 years, and Dr. Derek Denny-Brown as representative to the National Research Council for 3 years.

The 87th annual meeting will be held June 18-20, 1962 at the Claridge Hotel in Atlantic City, N. J.

THE WESTERN DIVISIONAL MEETING—APA.—The meeting will be held in Salt Lake City, Utah, Sept. 21-24th, 1961. An elaborate program has been provided :

Dr. Hardin Branch will moderate a symposium on the morning of Sept. 22, State Frontiers of Psychiatry, discussed by representatives of the various states.

The Academic lecture will be delivered by Dr. Henry W. Brosin at 1:00 a.m., Sept. 23.

A special feature of the meeting will be a "Tour of the Centre of Scenic America," beginning at 1:30 p.m., Sept. 22, 1961 and including a 7:00 p.m. Western dinner *en route*. The cost of this feature, covering afternoon and evening, is \$10.00 per person.

The West Coast Group Therapy Association meets concurrently Sept. 24, 1961.

CORRECTION

There was an error in the last sentence of the first paragraph of the book review of *American Handbook of Psychiatry*, edited by Silvano Arieti, page 1051, May 1961. That sentence should read :

There are useful contributions by Hans Strauss on Epileptic Disorders, by Henry Brill on Postencephalitic Conditions and on Psychoses with Huntington's Disease by Bigelow, Roizin, and Kaufman.

CREDULITY

Precious perquisite of the race, as it has been called, with all its dark and terrible record, credulity has perhaps the credit balance on its side in the consolation afforded the pious souls of all ages and of all climes, who have let down anchors of faith into the vast sea of superstition.

—OSLER

BOOK REVIEWS

CHILD AND JUVENILE DELINQUENCY. Edited by Benjamin Karpman, M.D. (Washington, D. C. : Psychodynamics Monograph Series, 1959, pp. 364. \$10.00.)

This book presents now in collected form the papers, comments and discussions that comprised 5 symposia held at Orthopsychiatric meetings in the early 1950's. The contributors were several outstanding workers drawn mainly from the psychiatric discipline.

The first 3 symposia deal with the somewhat vexed and uncomfortable concept of the child psychopath in terms of definition, etiology, psychopathological phenomena, frequency of occurrence and treatability. On only one of these points, the relatively gloomy prognosis, do nearly all speakers agree. For the rest, the opinions are as diverse as the approaches presented, which vary from the convinced endocrine-organic to the equally convinced psychoanalytic. It is, however, refreshing to find expressed by all, the present lack of any proven definitive statements or conclusions and a knowledge of the inadequacies of any and every approach to this thorny problem.

The latter 2 symposia deal with the more frequent delinquent problems, the first with the older and the second with the younger "predatory" delinquent. As in the first three, the contributors speak from a wealth of experience and add, by a variety of views, a roundedness to the consideration of "psychodynamics" and "basic emotional factors."

Although at times, the differences appear to be less of fact than of approach, there is little attempt to find any common ground and one is left with a series of well-stated convictions. No new ideas of any material consequence are presented—indeed, in its whole 368 pages, no tables appear except some profiles by Spitz. One can well empathize with Wechsler's lone cry in the wilderness for more rigid methods of research and verification. In addition, though there is common agreement on the importance of social factors, no voice is heard from the discipline of sociology.

It is impossible to discuss this book without referring to a grating tendency that increases throughout it, namely to summarize everything and then summarize the summary ad infinitum. This reaches its height of annoyance when the "summary" takes a complete sentence from the paper and repeats it—on the facing page (p. 124-125). Unfortunately, this detracts from the

real merit of the attempts to synthesize the divergent views that lie within these repetitious sections. The application of editorial rigor would have improved the overall value and impression even were it at the expense of the retention of spontaneity that publication "in full" may try to encompass.

Despite its drawbacks, the book represents a solid and conscientious attempt to present the many facets of work in the field at that time—a distillate of experience and opinion from those whose work entitles them to speak as representatives of a variety of divergent views.

EINFÜHRUNG IN DIE PSYCHIATRIE. By Kurt Kolle. (Stuttgart : Georg Thieme Verlag, 1960, pp. 92. DM. 6.80. \$1.60.)

Professor Kolle, who is director of the Psychiatric and Neurological Clinic of the University of Munich, has prepared three texts adapted primarily for use of medical students. This one may be regarded as a primer or guidebook to lighten the task of students coming newly into the psychiatric clinic.

Later on when the student has become somewhat acquainted with the subject and has seen many cases, he will need the more comprehensive and detailed text, the *Lehrbuch der Psychiatrie*.

Finally, to refresh his memory and make a closer study of cases he has seen in the clinical demonstrations he may turn to the third volume containing presentation of individual cases. In this last book Professor Kolle emulated the useful pattern of his predecessor, Kraepelin, in the latter's *Einführung in die Psychiatrische Klinik*.

In the present small *Wegweiser* Kolle begins with a brief notice of the main names in psychiatric history of the 19th and 20th centuries.

Next comes the subject of classification, the foundations of which were laid by Kraepelin, affording a system of medical diagnoses—*Ohne Diagnose Keine Therapie*.

The table of diagnoses in the narrower sense will however be confusing for the beginner. Therefore the author brings all psychic abnormalities together in 6 large groups: 1. Abnormal or psychopathic personalities. 2. Endogenic psychoses. 3. Exogenic psychoses. 4.

Acquired psychic disorders. 5. Diseases of the nervous system. 6. Disorders of the sympathetic nervous system. Brief commentaries accompany the several divisions.

It is necessary to acquaint the student with the dilemma of trying to align pathologic psychic states with somatic conditions. Innumerable futile attempts have been made to cut this Gordian Knot, which ultimately takes the shape of the body-mind question itself. To approach it by way of philosophy may satisfy the mind of the philosopher. Kolle mentions a late luminary in this field: Heidigger, whose existential philosophy has been seized upon by certain psychiatrists to resolve the dilemma. This area of speculation Kolle calls a "Nomansland," whence the spoils that adventurers bring home are only "*dürftig und einfürmig*."

Discussing diagnosis (3 pp.) Kolle contrasts the relative precision of diagnosis based on organic physical and neurologic findings with the extreme vagueness of diagnosis based on other factors.

Under treatment (24 pp.) is reviewed for the student all currently available procedures, including psychotherapy, with a somewhat ambivalent critique of psychoanalysis, together with methods that require institutional care. Opportunities for research are particularly stressed; likewise the standpoint that psychiatry and neurology constitute a united field as part of the whole discipline of medicine.

C. B. F.

RECENT ADVANCES IN BIOLOGICAL PSYCHIATRY.

Edited by Joseph Wortis, M.D. (New York & London: Grune & Stratton, 1960. \$13.50.)

To most British psychiatrists, too much American psychiatric literature now seems to consist of the repetitive dialectics of well-in-doctrinated Freudians, and therefore this book comes as a particularly welcome and appropriate reminder of the existence of a less vocal but very active minority striving for progress along lines much more likely to produce the new and really practical treatments of the mentally ill.

The book contains a veritable mass of facts and new observations along a variety of biological approaches to our psychiatric problems, and records what must have been a very special meeting of the Society of Biological Psychiatry in 1959. The Havelock Ellis Centenary, for instance, prompted an interesting symposium on sexual behaviour and impulse in man and animals, including a discussion of the importance of early imprinting as a cause of later

sexual deviation. There is also a most instructive round table discussion on the toxic theories of schizophrenia. The hallucinogenic drugs come in for special examination, including attempts to try to understand better the actual biochemistry of LSD psychosis. Kalinowsky appraises the tremendous practical treatment advances brought about by the somatic therapies, including the new tranquillizing and antidepressant drugs. Even the neurology of motivation is chosen for the Presidential Address, and a whole section of the book is devoted to a study of conditioning seen electroencephalographically in man and animals; other studies in neurology and physiology are given a whole 70 pages.

If only there were a few more volumes like this, we should certainly start to get very much nearer to helping a lot more of the patients now crowding the mental hospitals of both our countries.

WILLIAM SARGANT, M.D.,
St. Thomas' Hospital,
London, England.

THE CARICATURE OF LOVE. By Hervey Cleckley, M.D. (New York: The Ronald Press Company, 1957.)

In the preface to this little volume the author states:

"This book has two chief themes: sexual disorder and its influences, and a critical examination of some concepts of sexuality which are prominent today in psychiatry and psychology. Many psychiatrists, psychologists, and sociologists have, in recent years, taken the position that society should exhibit a more liberal attitude toward sexual deviation. It has been repeatedly maintained that the public and the law are unduly influenced by prejudice and archaic tradition, that aberrant sexual practices are too harshly condemned by our culture."

Dr. Cleckley obviously does not accept this point of view but regards personality disturbances of this type as distinctly abnormal and adds as a subtitle of his book: "A Discussion of Social, Psychiatric, and Literary Manifestations of Pathologic Sexuality." The chief, but not only form of sexual deviation which the author discusses, is homosexuality. He points out that many persons who have contributed much to literature and the arts and who in many respects have contributed to human values have satisfied sexual impulses in this manner. He does, however, in spite of the contributions which such persons have made, believe that persons who indulge in them must be regarded as having personalities which are

pathological and may exercise a disturbing influence on young associates. He quotes from the *Journal of the Americal Medical Association* as follows, in its reply to a question received a few years ago asking if homosexuality is thought to be congenital or acquired: "As such a child (homosexual) grows up he retreats from heterosexuality to homosexuality because of previous fearful associations with heterosexuality." We wonder if this is correct.

The experience of the author has been much like that of most of the rest of us: namely, that these sexual deviates are rarely treated successfully. We also agree with him that science should "avoid using such terms as 'prove' and 'demonstrate' for what is no more than hypothesis, personal taste or speculation."

As one lays down this book he feels somewhat puzzled as to its purpose. Is its purpose to present a really intelligent discussion of sexual deviations or is it to make sport of Freudian theories? Although many theories proposed by Freud seem to be baseless speculations, yet if they were considered as figures of speech instead of substantiated theories would they not receive more general acceptance?

ARTHUR P. NOYES, M.D.,
Norristown, Pa.

AND THE POOR GET CHILDREN. By Lee Rainwater, Ph.D. (Chicago: Quadrangle Books, 1960, pp. 190. \$3.95.)

Clinics affiliated with the Planned Parenthood Federation of America have been involved for many years with evaluation and prescription of contraceptive methods. Harmlessness, effectiveness and acceptability were the criteria used to evaluate such methods. Sufficient time has been given to prove the efficacy and reliability of the methods tested and prescribed. The concern now is that of acceptability. Various psychological investigations are in progress, or projected, to determine: Why those most in need of contraception do not seek it; why those who do seek it (and, in so doing, presumably demonstrate a desire to use the prescribed method) but then do not use it; and why some discontinue the method after a period of time.

In an attempt to answer these questions, the Planned Parenthood Federation of America sponsored a pilot investigation of the psychological factors involved in family planning and contraceptive practices among working class men and women. As stated, 2 broad subjects were covered. 1. Specific attitudes, motives and habits in connection with contraceptive practices. 2. The psychological context of motives, morals and attitudes in other aspects of family

living which condition working class behavior in the area of contraception. The sample consisted of 96 working class respondents, 46 men and 50 women, in the reproductive years, living in an urban area, constituting an ethnic and religious cross section, and all married and living with their spouses.

The findings show a concrete correlation between the factors explored and the use and non-use of specific contraceptive methods. Excerpts from some of the interviews are particularly revealing.

From these findings, the challenge is raised to all workers in this field. "It is clear that working class people have a real interest in family planning and limitation. The professional worker who is able to approach them in terms of their realities, their understanding, their anxieties, and goals will stand the best chances of helping them to use effectively their own self interest in contraception."

New York City.

AN EXPERIMENT IN MENTAL PATIENT REHABILITATION. By Henry J. Meyer and Edgar F. Borgatta. (New York: Russell Sage Foundation, 1959, pp. 114. \$2.50.)

This monograph is a carefully planned evaluative survey of an ambitious pilot project planned by the Executive Director of Altro Health and Rehabilitation Services Inc., Bertram J. Black. The project represented an extension of the services of this agency to include patients discharged from state mental hospitals. The research team narrowed down its selection of the group to be studied to those with the diagnosis of schizophrenia.

The express aim of the project was to determine whether the rehabilitation program offered by the agency, which is carried out and supervised in the environmental setting of a modern garment factory, could be adapted to the re-conditioning of discharged mental patients with the same success as with the after-care of discharged tuberculous and cardiac patients.

Despite the fact that there was a widely expressed conviction that there would be no difficulty in assembling a sufficient number of clients anxious to take advantage of the program, the fact proved to be quite the opposite, with the result that the numbers actually engaged in the rehabilitation were negligible. Consequently, the primary purpose of the project was not realized. From the ashes of defeat, however, rose a phoenix of resourceful

inquiry into the significance of what had been learned about the problems, attitudes, beliefs, and expectations of the clients who had been selected to form their "focal group" (those who would be put through the rehabilitation program) and the control group. Many pointers were found in these areas to suggest that there is a vast amount of work to be done in the field of studying the after-care needs of the discharged mental patient. Above all, it soon became evident that the availability of a potentially sound rehabilitation program does not by any means prove that there will be a waiting list of clients.

Although, therefore, this pilot project failed to produce statistical results of any significance with respect to the possible benefits of the Altro Rehabilitation program in re-conditioning the ex-hospitalized mental patient to meet the ardors of competitive living, a great many observations were made which will be of use to others who plan research in this complex area of human illness.

The application of work therapy for mental hospital patients is not a new or untried auxiliary therapy, either during hospitalization or later. This principle—the principle of re-conditioning disabled persons to the use of injured limbs or of impaired mental faculties through the acquisition of technical skills and the development of increasing work tolerance—has been in application in such widely different settings as the New York State Rehabilitation Hospital and the Rehabilitation Center of the American Rehabilitation Committee for many years. There is, I believe, ample proof of the usefulness of such rehabilitation programs in a wide range of human illnesses. It is well-known to workers in this field that the emotional factors involved in re-conditioning a sick person are of paramount importance, no matter what may be the diagnostic category in which the illness falls. In mental illness this factor is, of course, of absolute and primary importance.

Where this project calls for special commendation, however, is, first, that it represents an attempt at serious evaluation of whether, how, why, and when a certain program can be proven to be adapted to the after-care of ex-hospitalized mental patients; and, second, that the agency called on experts in the field of social science to co-operate with, advise on, and evaluate the implementation of the project. It is one thing for an agency to try to outline sound methods of procedure and to work steadily at implementing its program and at evaluating its own results. It is quite another to take full responsibility for planning

and carrying out a pilot research and to subject those who do the work to a continuing and final critical evaluation. Only by such genuine scientific enthusiasm and objectivity can advances be made in such a complex field as the rehabilitation of the ex-hospitalized mental patient. The staff of the agency, the evaluating team, and the Russell Sage Foundation are to be congratulated on a modest but valuable contribution to our understanding of some of the principal leads to be followed in future investigations.

JOHN A. P. MILLET, M.D.,
New York, N. Y.

THE TWO CULTURES AND THE SCIENTIFIC REVOLUTION. By C. P. Snow. (New York: Cambridge University Press, 1959, pp. 58.)

In this time of fast-moving social and political changes we are also enjoying (or enduring) a scientific revolution. Sir Charles Snow feels we are as unconscious of it, as poorly prepared for it and have it as weakly integrated socially as our forbears in the case of the industrial revolution. This latest movement is coming inevitably into our lives with changes causing more change resulting in farther revolution, and so on. At least that was the kind of sequence when there were new sources of power, new machines and when a new organization of production began in the 18th and 19th centuries. The earlier revolution was the cause of severe shocks to social systems and national structures, but it was, as Snow puts it, "the hope of the poor," because they at least had a chance of self-improvement though they first had to experience the sweat shops. This scientific revolution consisting of major advances in the electronic fields, atomic energy and automation will not be so important for destroying feudal systems and bringing down aristocracies as it will be hope for the poor nations of the world. The social and political upheavals provide the motives for major alteration in the social systems of Africa and Asia. The scientific revolution will provide the means for these changes which will *not* be evolutionary, gradual and spread over several generations. Instead, the people of Africa and elsewhere will soon learn they need not wait for their offspring to enjoy those things the major civilized nations now have. They will want them now or in the near future and their desires will be in the realm of possibility because of the scientific revolution. We have not the excuses of the past for delay and patience because technological advances will make progress a possibility much sooner than we had

expected. We can only hope to have influence upon the direction and shape progress will take in the previously underprivileged areas.

Sir Charles Snow in his Rede Lecture at Cambridge has such an immensely impressive message on matters of overwhelming importance in such reasonably cool language that this reviewer struggles to keep out the sound of trumpets in reporting on it. Snow is a remarkable and versatile man with careers in science, literature and government all of which qualify him for the particular angle used in this book.

A major aspect of our maladaptation to the scientific revolution and of our increasingly apparent inability to use it wisely for stimulating democratic advantage in the underdeveloped countries has been the traditional and growing schism between the humanities and sciences, between the literary men, writers and teachers on one side and the scientific researchers, teachers and technologists on the other. Snow feels these two groups, somewhat artificially dichotomized for his purposes, are as separate as two cultures and he is as an anthropologist reporting on them. From his quelled and reserved atmosphere the literary man has pity and contempt for the quick but shallow ways of the scientist. But the brash and brainy physicist, archetype of his group, with his chaotic blackboard has no time for the writer quaint and old-fashioned as he is, nor for his books either.

As Snow sees it there is both truth and blind prejudice in the opinions of each about the other. The writer is as illiterate about the periodic table as the scientist regarding modern poetry. The best of our writers have been determinedly last in perceiving and accepting social advance. Mistrust of the literary ones deserves sympathy because of the fusty and fiercely backward ideas propounded by Yeats, Pound, Eliot, Faulkner and Robert Penn Warren to mention a few. Then the scientist is too often lacking depth in his feeling and thought about the human condition and the needs and goals of men who are not scientists. The scientist's attitude with many exceptions is too likely to be impatient with things of non-scientific value and to assume that (except for music) art is a kind of plaything, unreal and quite secondary.

The mutually repellent nature of the relationship between these cultures has a disintegrating effect upon education and leads to specialization in trivia. This pulling apart also makes for a lack of ability to coordinate an

adaptation to the inexorable scientific revolution. These effects are described by Snow as major sources of the very dangerous delay in our work as humanists and scientists in the underdeveloped countries.

I think this book may be of particular interest to psychiatrists because they have in some ways struggled more than others with the division and coordination of humanistic and scientific disciplines.

College of Medicine,
University of Cincinnati.

THE SCIENCE AND MEDICINE OF EXERCISE AND SPORTS. Edited by Warren R. Johnson.
(New York: Harper and Brothers, 1960,
pp. 740. \$12.00.)

This is an excellent book for all those interested in the medical and scientific aspects of exercise and sports. Its 42 contributors include many whose primary interest lies in physical education, and in the physiology and psychology of exercise. All present their matter in a readable and well-referenced manner; an extensive bibliography following each chapter. The section on physiological aspects is factual and informative, dealing with each of the body systems, and presenting opinions backed with experimental studies of the effect of exercise on them, and the variations noted under particular circumstances; for example, stress, training, weight-control, climate, altitude and sport diving. The problem of motor development, growth, and exercise in adult years, with special reference to middle and advanced years, are well discussed. The psychological aspects are reviewed, with discussion of the personality dynamics, and the contribution of exercise and sport and of athletic participation to mental health and academic performance. The therapeutic aspects with relation to medicine, rehabilitation of the ill, and as a psychiatric adjunct are well presented.

Apart from the factual presentation of experimental and theoretical data and background, one cannot escape the feeling that the authors believe that exercise and sports are pleasant, worthwhile and beneficial activities, despite the fact that in no place are they guilty of biased presentation or of extravagant claims.

University Health Service,
Toronto, Can.

JACKSON, FREUD AND SHERRINGTON ON THE
RELATION OF BRAIN AND MINDRONALD W. ANGEL, M.D.¹

The first object of this paper is to show that John Hughlings Jackson, Sigmund Freud and Sir Charles Sherrington held remarkably similar views concerning the relation of cerebral and mental processes. The second object is to suggest that their views provide a sound rationale for current research on the neural basis of mind.

It is noteworthy that these men, who were leaders in neurology, psychiatry and neurophysiology, respectively, arrived at similar conclusions in regard to the brain-mind relation. Their reasoning is still cogent, and it deserves special interest in the present era of psychophysiology, psychopharmacology, psychosurgery and psychosomatic medicine.

Despite the recent upsurge of these hybrid specialties, the literature contains few explicit discussions of the brain-mind problem. In writings on neurophysiology, the word "mind" is usually enclosed within apologetic quotation marks, and in writings on psychoanalysis, the word "brain" seldom occurs at all. If these disciplines can progress without reference to the brain-mind problem, then why does it deserve serious attention?

One answer is that persons who study the brain or the mind are likely to make various assumptions concerning the relation between the two. Even if these assumptions are purely implicit, they tend to influence thinking and research. It would seem advantageous to make them explicit, if only in order to become aware of their defects and limitations. Jackson, Freud and Sherrington took pains to express their assumptions in clear, written statements. These writings form the basis of this paper.

HUGHLINGS JACKSON AND THE
DOCTRINE OF CONCOMITANCE

Hughlings Jackson drew a clear distinction between mental states, on the one hand, and nervous states on the other. In the class of mental states, he included perceptions,

thoughts, affects, wishes and so on. In the class of nervous states, he would include "the varying conditions of anatomical arrangements of nerve cells and fibers . . . the physics of the nervous system" (1). He objected strongly to the prevalent confusion of psychology with the physiology of the nervous system exemplified in such statements as that "ideas are formed in the cortical grey matter of the brain, and produce movements by acting on lower centers" (1). He warned against

the fallacy that what are physical states in the lower centres fine away in psychical states in higher centres; that, for example, vibrations of sensory nerves become sensations, or that somehow or another an idea produces a movement (2).

Despite his warning, this fallacy appears repeatedly in present-day writings on psychiatry. For example, in one standard text we are told that severe anxiety may overflow into the muscular system where it produces tremor and restlessness (11). Jackson would have no patience with statements of that kind.

Not only did he distinguish clearly between nervous and mental states, but he denied any transition from one to the other (1):

We cannot understand how any conceivable arrangement of any sort of matter can give us mental states of any kind . . . I do not concern myself with mental states at all, except indirectly in seeking their anatomical substrata. I do not trouble myself about the mode of connection between mind and matter. It is enough to assume a parallelism. That along with excitations or discharges of nervous arrangements in the cerebrum, mental states occur, I, of course, admit; but how this is I do not inquire; indeed, so far as clinical medicine is concerned, I do not care.

When Jackson stated that he was not concerned with the connection between mind

¹ VA Hospital, Hines, Ill.

and matter, he may have seemed indifferent to the mind-body problem. On the contrary, he faced it directly and expressed his viewpoint unequivocally. He recognized two classes of events, the mental and the physical, which are mutually exclusive. Mental states are connected in some way with their anatomical substrata, but he did not presume to understand the mode of connection. As shown in the following quotation, he denied that the relation is causal(3) :

Now, I speak of the relation of consciousness to mental states. The doctrine I hold is : first, that states of consciousness (or, synonymously, states of mind) are utterly different from nervous states; second, that the two things occur together—that for every mental state there is a correlative nervous state; third, that, although the two things may occur in parallelism, there is no interference of one with the other. This may be called the doctrine of Concomitance.

Jackson's doctrine of concomitance had a strong influence upon those who followed him, including Sigmund Freud.

THE VIEWS OF SIGMUND FREUD

Following Jackson, Freud drew a clear distinction between mental states and states of the brain. His viewpoint is expressed in the following quotation(4) :

The tendency of earlier periods in medicine was to localize whole mental faculties, as they are defined by psychological nomenclature, in certain regions of the brain. By contrast, therefore, it was bound to seem a great advance when Wernicke declared that only the simplest psychical elements, the different sensory presentations, could legitimately be localized—localized at the central termination of the peripheral nerve which has received the impression. But shall we not be making the same mistake in principle, whether what we are trying to localize is a complicated concept, a whole mental activity, or a psychical element? Is it justifiable to take a nerve fiber, which for the whole length of its course has been a purely physiological structure and has been subject to purely physiological modifications, and to plunge its end into the sphere of the mind and to fit this end out with a presentation or a mnemonic image? If "will," "intelligence," and so on, are recognized as being psychological technical terms to which very complicated states of

affairs correspond in the physiological world, can we feel any more sure that a "simple sensory presentation" is anything other than a technical term of the same kind?

It is probable that the chain of physiological events in the nervous system does not stand in a causal connection with the psychical events. The physiological events do not cease as soon as the psychical ones begin; on the contrary, the physiological chain continues. What happens is simply that, after a certain point of time, each (or some) of its links has a psychological phenomenon corresponding to it. Accordingly, the psychical is a process parallel to the physiological—"a dependent concomitant."

It is well known that Freud's earlier views on the relation between the mind and the nervous system were greatly influenced by Jackson, from whom he borrowed the phrase "dependent concomitant." Like Jackson, Freud warned emphatically against confusions between physical and psychical processes, and he would not tolerate thoughtless jumps between the physiological and psychological points of view. He objected, for example, to the statement that a mental "presentation" might be localized within a nerve cell(4) :

This way of putting matters . . . at once leads to a confusion between the two things, which need have no resemblance to each other. In psychology a simple presentation is something elementary for us, which we can sharply distinguish from its connections with other presentations. This leads us to suppose that the physiological correlate of the presentation—i.e., the modification that originates from the excited nerve fiber with its termination at the centre—is something simple too, which can be localized at a particular point. To draw a parallel of this kind is of course entirely unjustifiable; the characteristics of the modification must be established on their own account and independently of their psychological counterpart.

The views of Freud and Hughlings Jackson are seen to agree, except upon one point. Jackson spoke of "states of consciousness" as synonymous with "states of mind." Freud would disagree with him about this, but otherwise there is full agreement. Jackson sought physical explanations for disordered states of the nervous system; Freud sought psychological explanations for dis-

ordered states of mind, but neither would permit loose thinking upon the relation of brain to mind.

Just as Hughlings Jackson protested against the use of psychological terms in explaining neurological disorders, so Freud and his followers objected to the use of physiological terms in psychology. Breuer, for example, wrote as follows(5) :

In what follows little mention will be made of the brain and none whatever of molecules. Psychological processes will be dealt with in the language of psychology ; and, indeed, it cannot possibly be otherwise. If instead of "idea" we chose to speak of "excitation of the cortex," the latter term would only have any meaning for us in so far as we recognized an old friend under that cloak and tacitly reinstated the "idea." For while ideas are constant objects of our experience and are familiar to us in all their shades of meaning, "cortical excitations" are on the contrary rather in the nature of a postulate, objects which we hope to be able to identify in the future. The substitution of one term for another would seem to be no more than a pointless disguise. Accordingly, I may be forgiven if I make almost exclusive use of psychological terms.

This is a clear statement of the lesson taught by Jackson and Freud : thoughtless transitions between the psychological and physiological points of view can serve no useful purpose. If contemporary writers would remember this lesson, one would no longer read about the overflow of anxiety into the muscular system or the effect of morbid ideas upon gastric secretions.

THE VIEWS OF SIR CHARLES SHERRINGTON

Like Jackson and Freud, Sherrington emphasized the distinction between mental and physical processes, as shown in the following statement(6) :

The physico-chemical (or for short physical) produced a unified machine from what without it would be merely a collocation of commensal organs. The psychical, creates from psychical data a percipient, thinking and endeavouring mental individual. Though our exposition kept these two systems and their integrations apart, they are largely complementary and life brings them co-operatively together at innumerable points. Not that the physical is ever anything

but physical, or the psychical anything but psychical.

Sherrington goes on to point out the difficulty that must be overcome in the attempt to integrate brain and mind.

[This integration] has to overcome a difficulty of no ordinary kind. It has to combine two incommensurables ; it has to unite two disparate entities. To take an example : I see the sun ; the eyes trained in a certain direction entrap a tiny packet of solar radiation covering certain wave-lengths emitted from the sun rather less than 10 minutes earlier. This radiation is condensed to a circular patch on the retina and generates a photo-chemical reaction, which in turn excites nerve-threads which relay their excitation to certain parts of the brain, eventually to areas in the brain-cortex. But . . . there follows on, or attends, the stage of brain-cortex reaction an event or set of events quite inexplicable to us, which both as to themselves and as to the causal tie between them and what preceded them science does not help us ; a set of events seemingly incommensurable with any of the events leading up to it. The self "sees" the sun ; . . . in the sequence of events a step is reached where a physical situation in the brain leads to a psychical, which however contains no hint of the brain or of any other bodily part . . . The supposition has to be, it would seem, two continuous series of events, one physico-chemical, the other psychical, and at times interaction between them.

This is the body-mind relation ; its difficulty lies in its "how" . . .

Sherrington thus agreed with Jackson and Freud that mental and physical events are distinct and incommensurable. He disagreed with them when he stated that there may be interaction between the two series of events, although he found it difficult to conceive how such interaction occurs. All three writers would surely agree that there is at present no known means of interaction.

OTHER POINTS OF VIEW

The doctrine of concomitance is not, of course, the only possible viewpoint concerning the body-mind relation. By way of contrast, some of the other proposals will be mentioned, although it is not within the scope of this paper to discuss them adequately.

The simplest, though not the most respectable, way to handle the relation between body and mind is to deny the existence of one or the other. Certain faith-healers, for example, profess to believe that the material world is an illusion. Since, in their view, the material body does not exist, there can be no problem of a body-mind relationship. Surely no one in the medical profession would accept this doctrine, and it need not be discussed further.

A second proposed solution is to deny the existence of mind. This approach is taken by the behavioristic psychologists, who either deny the occurrence of mental states or reject them as irrelevant. According to the followers of John B. Watson, the objective facts of human and animal behavior comprise the only proper subject for psychological study. For them, as for the faith-healers, there can be no problem concerning the relation of body and mind, since there are not two variables to be related.

Although Watsonian behaviorism has passed its heyday, a behavioristic bias is still evident in animal psychology. Since the lower animals have no speech, one cannot record their inner experiences nor even verify that such experiences occur. The animal psychologist records only the overt behavior of his subjects, together with any related electrical, mechanical or chemical changes. Yet he cannot ignore the animals' inner life entirely. In some experiments the cat may act as if it were "hurt" or enjoying a pleasant experience (7). In recording such observations the animal psychologist may put quotation marks around the words "hurt" and "experience," but he has to depart from the purely behavioristic viewpoint. Thus it appears that a thoroughgoing behaviorism is no longer appropriate, even in animal psychology.

A third proposed solution to the body-mind question is to dismiss it as a pseudo-problem based upon linguistic confusion. According to Professor Ryle (8) and other philosophers of the Oxford school, the distinction between mind and body is purely a matter of language. The word "mental" does not apply to a special kind of "stuff" but only to certain organizations or patterns of elements which it is not significant to call "mental." Bertrand Russell (9) has written

a cogent refutation of these philosophers, who try to dismiss important scientific problems as verbal trivialities.

A fourth proposed solution is the two-aspect theory, whose proponents would deny the "medically useless" distinction between mind and body (10). According to this theory the mind is "merely one aspect—the psychological aspect—of biological functioning of the organism" (11). Behavior that involves the organism as a whole is called mental. Behavior that involves only a part of the organism is called physical. Since there is no real dichotomy, there can be no problem of a body-mind relationship.

This theory invites criticism for two reasons. In the first place, the definitions of mind are unsatisfactory. We are told that mind is merely the psychological aspect of biological functioning. "Psychological," of course, means "of or pertaining to psychology," and psychology is the study of the mind. The definition is, therefore, circular. With equal cogency one might define "digestion" as "the gastroenterological aspect of biological functioning."

The other definition of mind, as a collective term for activities that involve the organism as a whole, is no more satisfactory. According to this definition, any behavior that involves the coordinated activity of the whole individual, including the special senses, brain, musculo-skeletal system and viscera must be called mental. Any activity that involves just one part of the organism, for example the brain, must be called physical. This leads to the curious conclusion that playing tennis is a mental process whereas daydreaming is a physical activity.

The second defect of the two-aspect theory is illustrated by the following analogy: If one were asked to explain how the therapeutic actions of a certain drug are related to its chemical structure, he might reply that there is no real dichotomy between chemical structure and therapeutic actions, that the two are merely different aspects of a chemotherapeutic unity. This kind of reply is unacceptable since it attempts to answer a question of fact by means of verbal evasion.

The relation between cerebral and mental processes is a question of fact. It is a fact that human beings have brains, which are

exceedingly complex, both in structure and in function. It is also a fact that people have sensations, thoughts, emotions, wishes and dreams. In ways that we are only beginning to understand, these mental processes are correlated with the structure and function of the brain. Workers in psychophysiology and psychopharmacology are now trying to map out the details of this correlation. They can expect no help from the two-aspect theory, which attempts to brush aside the very problem that they are studying.

Proponents of the two-aspect theory might accuse Jackson, Freud and Sherrington of setting up the mind as a metaphysical entity. The charge is, of course, untrue. These men were not metaphysicians but practical scientists who insisted upon clear thinking. Indeed, the clarity of their views invites mathematical formulation. Using techniques developed by Russell, Woodger (12), Carnap (13) and others, it is now possible to apply mathematical reasoning in any field where relations play an essential role, *e.g.*, the various geometries, physical theories and, most recently, certain branches of biology. Jackson's doctrine of concomitance provides a starting-point for an exact logical formulation of the body-mind relation.

When contrasted with rival theories, Jackson's doctrine is not only clearer but also more useful as a basis for experimental research on the neural basis of mind. It postulates that for every mental state there is a correlative nervous state. If we modify this to read that every *kind* of mental process is correlated with a specific *kind* of cerebral process, then we have a rationale for psychophysiology. What kind of cerebral activity is correlated with the experience of pain or pleasure? What are the neural substrata of perceptions, thoughts, wishes and dreams? To answer these questions, or even to ask them, we must have some rationale such as that provided by the doctrine of concomitance.

SUMMARY AND CONCLUSIONS

Hughlings Jackson, Sigmund Freud and Sir Charles Sherrington held similar views concerning the relation of brain and mind. Jackson and Freud believed that physical and mental processes comprise two distinct series of events, which are closely related but do not interact. Both men objected to the prevalent confusion of psychology with the physiology of the nervous system. Sherrington agreed that physical and mental processes are "incommensurable," but he believed that interaction is possible.

When contrasted with rival theories, the doctrines of these men appear to be more acceptable, both logically and as a rationale for experiments on the neural basis of mind.

PSYCHOSIS, DRIVE AND INHIBITION : A THEORETICAL AND EXPERIMENTAL ACCOUNT ¹

H. J. EYSENCK ²

INTRODUCTION

For the past 10 years or so the writer and his colleagues have been attempting to discover objective psychological tests in the cognitive, perceptual and motor fields which would differentiate psychotic patients from normal subjects and neurotic patients of similar age, sex and intelligence (10, 11, 15, 20). It was discovered that quite large numbers of tests did in fact differentiate the psychotic groups from the others, and it was further found that the one feature which all these tests seemed to have in common was a generalised pattern of slowness which seemed to cover the areas of perception, cognition and motor reaction (35). These results fit in rather well with those obtained by many other investigators (1, 2), and recent reviews have adequately covered this field so that it will be unnecessary to do so again here (17).

Another outcome of the series of researches mentioned above has been to clarify the *dimensional description* of mental abnormality. Analyses of objective test scores made by schizophrenic, manic depressive, hysterical, psychopathic, anxious, obsessional and depressed patients, as well as normals, have shown clearly that these diagnostic categories did not in any sense refer to *categorical disease groups* but are rather located at various points of a 3-dimensional framework, the three axes of which are psychoticism, neuroticism, and extraversion/introversion. These analyses have been carried out by making use both of factor analysis and of multiple discriminant function analysis, and the results of these quite divergent techniques have been astonishingly similar (10, 11, 13, 14, 18, 24, 36).

As regards the descriptive or nosological side of the investigation, therefore, the results seem to be clear-cut and relatively straightforward. Psychotic disorders are essentially unlike neurotic disorders; both

manic depressive and schizophrenic patients react very similarly on large batteries of objective tests; and it is possible to generalise a large number of different experimental findings by stating that psychotic subjects, in every aspect of their behaviour, tend to be abnormally *slow*. This statement of course does not exclude the possibility that psychotic subjects are also characterised in other ways which may not themselves depend on generalised slowness; it has however been our experience that many of the symptoms of thought and behaviour disorders of psychotic patients can ultimately be reduced to derivatives of general slowness. It is also not intended to convey the impression that there are no differences between schizophrenics and manic depressives; recent studies from this laboratory have indeed provided significant evidence of differentiation between these two groups (17, 36). Nevertheless, as far as mental slowness is concerned, both the two major groups of functional psychotics appear to be characterised by very similar reactions, and it will be the purpose of this paper to suggest a theory to account for these findings.

The sequence of events leading from psychiatric nosology through psychometric and empirical objectification to hypothetico-deductive theoretical and experimental analysis duplicates that which has characterised the set of studies carried out in the field of neurosis (9, 15, 18), and it is interesting to note that in the neurotic field this type of progress finally led to the elaboration of a rational system of classification, diagnosis and therapy (19). It is the writer's belief that advance in abnormal psychology and psychiatry is most likely to come by the pursuit of some such series of steps, and it may not be entirely fanciful to imagine that problems in the aetiology and treatment of psychosis may in the long run also find an answer along these lines.

THEORETICAL ANALYSIS

The concept of *explanation* in psychiatry

¹ The writer is indebted to the Society for the Investigation of Human Ecology for a grant in support of the studies here reported.

² Institute of Psychiatry, University of London.

and psychology has always presented some difficulties. It is customary to explain the less well-known by the better known, but in the field of the social sciences there has been so little agreement on what is known and what is merely hypothetical that it proved impossible to follow the usual course of scientific explanation. The writer (15), has argued that the recent advances in modern learning theory (26, 39) have furnished us with a set of concepts and laws which, while far from perfect, are nevertheless sufficiently precise and well validated to make it possible to account for behavioural observations in terms of these concepts and laws, and to make experimentally testable deductions from such theories. Hitherto the writer has concentrated on neurotic disorders in his attempts to apply modern learning theory to psychiatry (15); the present paper is a first attempt to make such an application to the field of psychosis.

Without entering into all the complexities which a detailed analysis along Hullian lines would necessitate, we may perhaps state quite broadly that most modern learning theorists would agree with some such statement as this :

$$P = (f) D \times H;$$

i.e., performance is a multiplicative function of *drive* and *habit*. *Drive* in this formulation means the motivational state of the organism which makes it perform the task in question, while *habit* relates to the particular connexions in the central nervous system which have been made through previous learning and which facilitate the performance in question. One immediate hypothesis which arises from this formula would be one which would account for the worse (slower) performance of the psychotic in terms of lower drive; indeed, this is of course the type of explanation which is normally given in text books of psychiatry and clinical psychology.

An alternative hypothesis suggests itself when we consider an additional concept, namely that of *reactive inhibition* (usually abbreviated and symbolised as I_R). This is conceived to be a kind of neural fatigue, of central origin, which develops after any kind of perceptual, cognitive or motor performance and dissipates in time. During massed practice this inhibition accumulates,

as there are no rest periods during which it can disappear. Now I_R , which subjectively is experienced as boredom, fatigue or even pain, is regarded as a negative drive, *i.e.*, a tendency to make the organism stop doing whatever it is doing. As such it is subtracted from $D(30)$, so that the "drive" in our original equation is really equal to $(D - I_R)$; this combination of positive and negative drive may be symbolised as D (effective drive).

We now have an alternative hypothesis to account for the poor performance of psychotics. We may assume that reactive inhibition either accumulates faster or dissipates more slowly in psychotic patients or both; this would leave them in a state of lower D , even though they were equal or even superior to normal and neurotic subjects with respect to D . As inhibition grows fairly quickly even in normal subjects, the main interest of this hypothesis would centre on the hypothesised *slower rate of dissipation*, and in order to account for the very marked differences in behaviour between psychotics and other groups it would be necessary for this slowing down in the rate of dissipation to be quite severe. We thus end our consideration of theoretical possibilities with two alternative hypotheses, both or either of which would, if true, explain a good deal of psychotic behaviour :

1. Psychotics have lower D (motivation) than normal or neurotic subjects.
2. Psychotics have a slower rate of dissipation of I_R (reactive inhibition), and are consequently nearly always working under a lower D (effective drive).

It will be the task of the next section to deduce from general learning theory certain consequences, experimentally testable, which should follow if these hypotheses were true, and demonstrate that in fact these deductions are borne out.

DEDUCTIONS FROM THE THEORY

In order to test the two hypotheses outlined above it is clearly necessary to be able to measure drive and reactive inhibition. Measurement of I_R fortunately presents little difficulty in principle. During massed practice I_R accumulates, because there are no rest pauses during which it can dissipate.

If now we introduce a rest pause into the proceedings sufficiently long for all or nearly all of I_R to dissipate, then we would expect an improvement in performance after the rest pause. This prediction is based on the simple consideration that before the rest pause $D < D$, because $D = D - I_R$. After the rest pause, however, $D = D$, because I_R has disappeared completely. Now H is not affected by the rest pause, and consequently the product of $D \times H$, i.e., the performance of the subject, will be greater after the rest pause than before. This well-known phenomenon is called *reminiscence*, a name given to it for historical reasons which would not recommend themselves to modern investigators, but which have embedded the term so firmly in our theoretical framework that it would be impossible to dislodge it now(34). We may say then that reminiscence can be used experimentally as a measure of I_R , provided certain simple conditions are fulfilled.

It has also been proved possible to use reminiscence as a measure of motivation or D . The early theoretical and experimental work of Kimble(31) and Wasserman(43) is relevant here. Kimble argued that reactive inhibition during massed practice would increase until it reached the same level as D . At that point $I_R = D$ and consequently $D = D - I_R = 0$. According to our formula performance should stop at this point as the equation would read: $P = 0 \times H$, which is itself zero. Accordingly at this point there would occur involuntary rest periods (I.R.P.s) during which the organism ceased functioning and during which inhibition would dissipate. When sufficient inhibition had dissipated for D to be a large enough positive quantity, performance would begin again, I_R would accumulate once again, thus enforcing another rest pause. From the moment that the critical point had been reached where $D = I_R$, the organism would therefore continue working in a series of fits and starts. There is good experimental evidence for the reality of such involuntary rest pauses in the analysis of behaviour(3, 4, 25, 33, 37, 42) and also in the electro-physiological analysis of EEG and other autonomic measures which demonstrate a momentary sleep-like state of the organism during these I.R.P.s

(44, 5).

If the critical level at which these involuntary rest pauses begin occurs at the point where $D = I_R$, then an organism working under low drive would clearly reach the critical level earlier than an organism working under high drive, and equally the amount of I_R tolerated by the organism working under high drive would be greater than the amount of I_R tolerated by an organism working under low drive. This is illustrated in Figure 1, with the letters H and L referring respectively to groups of subjects having high and low motivation.

FIGURE 1
Diagram Representing Theoretical Growth of Reactive Inhibition (I_R) in High Drive and Low Drive Groups, Leading to the Occurrence of Involuntary Rest Pauses (I.R.P.s) (21)

It will be seen from Figure 1 that after 6 minutes or so of practice both the high and the low drive group have reached their respective critical levels where $D = I_R$. Now we have already established that reminiscence is a good measure of I_R ; in other words $\text{reminiscence} = (f) I_R$. We have also seen that at the point where involuntary rest pauses begin, and from thence onward, $I_R = D$. We can take these two equations together and make them read: $\text{reminiscence} = (f) D$; in other words the amount of reminiscence observed under the experimental conditions described is a function of the drive under which the organism is working.

That this hypothesis is correct can be seen from Figure 2 which is a summary of two studies carried out by Eysenck and

Maxwell(21) and Eysenck and Willett(22) working with fairly large groups of industrial apprentices under conditions of high or low motivation respectively; these workers used as their experimental task the pursuit rotor. Rest pauses of 6 minutes were introduced at different points of practice for different groups of apprentices; as will be seen in Figure 2, the rest pause was introduced either after 2, 3, 6, or 8 minutes of practice. As predicted, the reminiscence scores of the low drive group remained at the same level throughout; those of the high drive group however grew as a straight-line function of length of practice. We may conclude therefore that reminiscence is indeed a good measure of drive under certain specified conditions.

FIGURE 2

Reminiscence Scores of High Drive and Low Drive Groups Giving Programmed Rest Pauses of Six Minutes after Massed Practice Lasting Two, Three, Six, and Eight Minutes, Respectively(22)

EXPERIMENTAL PROOF OF THE THEORY

We are now in a position to test our theory directly in relation to the performance of psychotic groups. First let us consider the kind of prediction which follows from both our two hypotheses. According to the first hypothesis, psychotics are characterised by *low drive*, and in view of the extreme nature of their performance defects we would have to postulate a very low drive state indeed to account for the defects. If this were true then it would follow directly from the considerations advanced in the last section that psychotics would have very little or no reminiscence *regardless of the length of the rest pause*, while normal and neurotic subjects under similar conditions would have reasonably high reminiscence scores. This result, it should be emphasised, would be expected to hold true regardless

of the actual level of performance of our psychotic groups. It is one of the advantages of the method of measurement of motivation suggested here that differences in ability or previous training on the task do not affect the measurement to any considerable degree as reminiscence is measured in terms of relative change from pre-rest to post-rest performance, and not in absolute terms.

A similar prediction can be made from our second hypothesis. The phenomenon of reminiscence as produced by the dissipation of I_R ; if, as the hypothesis states, I_R does not dissipate to any extent during the rest period in psychotics, then reminiscence would be low or nonexistent. We see therefore that both hypotheses predict unequivocally the absence of reminiscence in psychotic groups under conditions where reminiscence is clearly observed in normal and neurotic groups.

Two studies have been carried out in our laboratory giving strong support to this deduction from our theory. Broadhurst and Broadhurst(6), using both schizophrenic and manic depressive subjects of a chronic kind, demonstrated the complete failure of these subjects to show reminiscence effects on the pursuit rotor. At the same time, and quite independently, Claridge(7), also using the pursuit rotor, found a similar failure of reminiscence to appear in pursuit rotor performance on the part of young and undeteriorated schizophrenics (cf, Figure 3). Other investigations from the Institute of Psychiatry(40, 41) have also been interpreted in a similar manner although the results were not quite as clear-cut; this may have been due to the use of tasks less well suited than the pursuit rotor to the measurement of reminiscence. We may conclude therefore that the deductions from the general theory outlined in a previous section have good empirical support. It is interesting to note at this point that early investigations by Hoch(27) and Kraepelin(32), using the ergograph and the *Rechenheft*, suggested theoretical solutions not essentially different from those here attempted. These early studies were not adequately controlled, of course, and the type of activity studied did not produce results particularly well suited for this kind of analy-

sis, but nevertheless the early emergence of experimental tests related to theories of drive and inhibition (fatigue) should not be passed over without comment.

FIGURE 3

Experimental Data Showing Lack of Reminiscence in Psychotic Subjects as Compared With Normals(7)

A CRUCIAL EXPERIMENT TO DECIDE BETWEEN THE TWO HYPOTHESES

The results so far reported would follow regardless of which of our two theories happened to be correct. We must now consider the possibility of designing an experiment to discriminate between the two theories. It has been pointed out in the last section that if the first hypothesis were true, *i.e.*, that accounting for psychotic performance in terms of low drive, then reminiscence scores should be low for psychotic subjects regardless of the length of the rest period. This, however, would not apply to our second hypothesis, which postulates that inhibition in schizophrenics would dissipate very much more slowly than in normals and neurotics. If the second hypothesis were true, therefore, we would expect that after a rest period of, say, 24 hours psychotics also would show strong reminiscence effects. Here then we would appear to have a crucial test to decide between our two hypotheses. It might of course be possible that both hypotheses were correct; in that case we would find a certain degree of reminiscence in psychotics after a 24 hour rest period, but this would still be below the reminiscence scores of comparable groups of normals and neurotics. The difference between the reminiscence scores of these groups would then

give us a measure of the difference in D . It would also be possible of course to record the rate of dissipation of I_R in psychotics by varying the length of the rest interval (30 minutes, 1 hour, 6 hours, 12 hours, 24 hours, *etc.*); this should enable us to plot in detail the decline of I_R and demonstrate in a quantitative fashion the differences between psychotics and other groups. It should also be possible to use reminiscence measures of this type as an index of recovery, assuming that recovery from psychotic illness was indeed accompanied by a lessening in slowness and an increase in D , or an increase in the speed of dissipation of I_R .

Some preliminary data are available with respect to the crucial experiment here proposed. Ley, in an unpublished study, tested 10 psychotic males with a rest interval of 10 minutes on the pursuit rotor, and another 10 with a rest interval of 24 hours. He also tested two groups of 10 normal subjects with 10 minute and 24 hour rest pauses respectively. He found at a good level of statistical significance that while after the 10 minute rest pause the normals had high positive reminiscence scores, those of the psychotics were for practical purposes equal to zero. After 24 hours he found that the reminiscence scores of the normals were somewhat lower than after the 10 minute rest pause; those of the psychotics however were now *higher* than those of either of the two normal groups. It would appear, therefore, that the hypothesis relating psychotic behaviour to low drive is untenable and that we must conclude that psychotic reactions are characterised by an excessive slowness of dissipation of inhibition.

This conclusion is supported by a recent study by Rachman (38), in which he had 10 chronic schizophrenics perform on the pursuit rotor with a rest pause of 10 minutes, while another group of schizophrenics performed with a rest pause of 24 hours. As pointed out above, normal subjects under these conditions show less reminiscence after the longer rest interval; as will be seen from Figure 4, the schizophrenics produced the opposite effect, with the 24 hour period significantly superior to the 10 minute one with respect to the size of the mean reminiscence score. Rachman's subjects

were all *male* patients of long standing; he benefited from Ley's finding that the poor performance of women generally, allied to the poor performance of schizophrenics generally, makes it almost impossible to test theories of this kind in schizophrenic women, as their performance does not easily leave the chance level; in order to work with women, the task has to be simplified, either by slowing down the rate of rotation of the target disc, or by enlarging the target disc. This has not to our knowledge been done hitherto.

FIGURE 4

Diagram Showing Lack of Reminiscence After Ten Minute Rest Pause(38)

It is possible to look upon the reports of Huston and Shakow(28, 29), supplemented by those of S. B. G. Eysenck(23), as providing some further support for the theoretical view under consideration. Huston and Shakow found with psychotic patients that reminiscence effects appeared after several months, using the pursuit rotor, while Eysenck failed to find such effects in normals after periods of 12 months. The analyses carried out by these workers are not sufficiently similar to place too much weight on the findings, but as far as they go they do seem to support the notion of slow rate of dissipation of Ir in psychosis, rather than that of lack of drive.

The negative conclusion of these studies regarding the lack of drive in psychotics is in good agreement with the results of another experiment(13) in which the persistence of psychotics on mental tasks was compared with the persistence of neurotics and normals, the assumption being that persist-

ence is to some extent a measure of drive. It was found that psychotics were significantly more persistent, as well as much slower. Elsewhere Eysenck(16) has shown that slowness in problem solving is a function of Ir. While this experiment on persistence is less conclusive than the series of experiments reported here, it nevertheless points in the same direction and may be used to strengthen the point made.

We may conclude therefore from this series of studies that an important aspect of psychotic behaviour is related to, and possibly caused by, the slow rate of dissipation of reactive inhibition in psychotics. It must remain the task of further experimental studies to verify these results, to indicate to what extent they apply to other types of test, to show to what extent the rate of dissipation of inhibition can be used to account for the observable defects of the psychotic, to what extent this rate is amenable to change by different types of treatment, and to what extent it mirrors the clinical state of the patient. This is a formidable list of research projects, to which should be added one additional project which takes us right out of the field of psychological investigation. There appears to be some evidence suggesting a link between inhibition and the activity of the ascending reticular formation(8), and a study of this link, with the slow rate of dissipation of inhibition of psychotics particularly in mind, would seem a very worth-while task.

SUMMARY AND CONCLUSIONS

An attempt has been made in this paper to account in theoretical terms for the generalised slowness which has been shown in previous work to characterise psychotic patients. Making use of the theoretical framework of modern learning theory, two hypotheses were put forward, relating psychotic slowness respectively to: 1. Lack of drive (motivation); 2. An exceedingly slow rate of dissipation of reactive inhibition. It was deduced from the theorems of learning theory that psychotics should be characterised by very low reminiscence scores on tasks involving massed practice if either of the two hypotheses were correct, and experimental evidence does indeed show that psychotics are differentiated from normals

and neurotics in precisely this way. It was then argued that a crucial test between the two hypotheses could be performed by varying the length of the rest period used for establishing reminiscence scores, and it was found that while with *short* rest periods psychotics showed *no* reminiscence, they did show very *strong* reminiscence effects after *long* rest periods. This is interpreted as irreconcilable with the hypothesis of low drive in psychotics, and may be used as support for the hypothesis that *psychotics are characterised by a slow rate of dissipation of inhibition*.

"PRIVATE" VERSUS "PUBLIC" LOGIC : SOME ANTHROPOLOGICAL AND PHILOSOPHICAL REFLECTIONS ON THE PROBLEM OF MENTAL "HEALTH"

ERNEST BECKER, Ph.D.¹

The recognition of cultural factors as an inseparable part in the psychodynamics and content of behavioral dysfunction had a quiet anthropological start. But as sociological and anthropological facts become the property of psychiatrists a new swell of theory seems to be threatening not only psychiatric nosology, but the very concept of "mental illness" (1).

In their search for clarification of a new and knotty problem, psychiatrists are showing themselves excellent historians, anthropologists, and even political theoreticians. The status of science as a humanity stands to profit considerably thereby. In a recent article, Carothers postulates that one of the important factors in shaping patterns of mental breakdown is the existence or lack of literacy in a given society (2). The attitude that a society has toward reality depends upon whether its repertory of symbols is oriented to the visual or to the auditory senses. Where a written tradition does not exist, the word tends to be magically concretized; thought undergoes embodiment, spills from the private into the public domain in the form of malevolent sorcery. One has only to think evil for evil to exist. It is thus that thought becomes socially dangerous, and must be curbed in the communal interest. With the advent of social literacy, on the other hand, the orientation to reality shifts to the visual; thought loses its embodiment and magical powers, and thinking and logic are allowed to pursue a socially useful autonomy in each individual. This, all too briefly, is Carothers' thoughtful thesis.

Anthropologists have long been grinding (albeit, unfortunately, out of public view) their own axe on the problem of primitive versus non-primitive mentality. In an attempt to show that there is no graded hierarchy from primitive "pre-logic" to civilized "logic," Radin, over 30 years ago, insisted

that the only difference lay in the written word and the technique of thought elaborated thereby (3). Even though nothing, therefore, is "new," significant facts are worth repeating, and Carothers' reexamination of the problem of literacy from a psychiatric standpoint serves again to provoke needed speculation and study.

But there is some discrepancy between Carothers' data and Radin's. For example, Carothers indicated that thought in primitive societies is received by the ear, rather than the eye, one reason perhaps for its ready concretization. And he concluded, as briefly indicated above, that since the word can have a magic power and easy embodiment, thought becomes socially dangerous and is curbed by the community. Carothers allows for non-African discrepancies in this picture of social coercion derived from magical beliefs about the power of sound. Radin's conclusions highlight just such discrepancy. From his American Indian experience, he postulated that a remarkable freedom of thought can exist on the "primitive" level (4). Compare the following with Carothers' African observations :

I would be the last to deny that primitive man attaches importance and power to mere thinking or to magical formulae. The fact is patent. All I wish to emphasize is that he does not believe that thought does more than validate the reality of his subjective life. It does not touch the two great realities which apart from his personality concern him most : . . . the reality of the phenomenal world and the social world (5). [Again :] Very frequently, indeed, one finds primitive man claiming to have been able to achieve certain results through the insistence and perseverance of his thoughts. I myself was once informed by an Indian that he had always been so successful on the hunt because he *used* his thought. Now concretization of thought is common enough among primitive people just as is the concretization of the emotions. Never, however, did thoughts *lose their primary character of proofs of reality* (6).

¹ Instructor, Department of Psychiatry, State University of New York Upstate Medical Center in Syracuse.

This discrepancy between African and American Indian data seems glaring; but it is superfluous to note that where matters of emphases are involved, which seek to support a conceptual orientation, interpretation of the facts shapes them somewhat to one's own use. Radin does not deny that the primitive man says, "I think, therefore, what I think exists" (7). But he insists that in the primitive's view, this subjectivity must not be interfered with: "If by expressing it he destroys himself, that is his own affair" (8). Thus, says Radin, "... it makes no difference whether a man thinks so or so. The social reality is not altered by it" (9). This freedom of thought is "... due to the clear preception of a lack of contact between thoughts, ideas, and opinions on the one hand and the social realities on the other" (10). The American primitive, in other words, seems to adhere to the adage, "He whom the Gods would destroy, they first make mad." The madness here lies in the subjectivity of thought, the ability of the individual to destroy himself by it; and it is held that self-destruction is discrete from the social reality.

It is our contention that since the primary function of thought is reality-testing for survival, this function finds its most direct exercise on those levels of existence where life is precarious. It is this that Radin's Winnebago recognizes: introverted thought that does not test itself against social reality is a private and perhaps even a self-destructive matter. But that is the individual's own concern, since, if he desires to survive, he had best come back into a social existence. After all, as we shall examine below, not all human groups have been as insistent as we are today upon preserving every single individual in the group.

The purpose of this paper is to draw a distinction between preliterate, social reality-testing for survival, and literate, logical testing of private propositions which have little if any relationship to survival in an immediate sense. But before proceeding to this, it would be helpful to review one model of the basic function of thought in reality-testing.

SCIENTIFIC INFERENCE AS THE BASIC COPING SKILL

The main task of the emerging individual

is the discovery of himself and the world. Reality-oriented from the first (Fairbairn's view), the infant tries to surmise boundaries and depths, especially of self and objects. By taking the attitudes of others toward himself, by "identifying" with the object, the child gives his own body an outside, and at the same time apprises the necessary inside of the flat, external object which is ministering to his needs. The world comes to be seen in the round.

But reality-testing does not continue smoothly. The environment causes frustrations, which give rise to conflicting impulses and inhibitions, and a new task is posed. The infant must find out what the novel features are in the new frustrating situation, in order to organize a response. This response, once organized, follows the conservatism of all organisms: it tends to be pertinent not only for the particular individual, but also for others. Thus, two new ideational components come into being: analysis of the unfamiliar, and representation of it in a generalizable direction. This play of ideas for coping with reality—analysis and representation—is internalized as a trial and error method within the individual, and thought and reflection become new tools for facilitating conduct.

These are George Herbert Mead's ideas, and he extended them in his understanding of the scientific method itself, and so put the method back into proper, exoteric perspective. Frustration arises when we meet a problem in thought, action or feeling, or an inhibition or exception to accustomed conduct. Our reaction to the new situation is characterized by a certain opposition of feelings—the same inhibition that the infant feels in the face of his frustration at something new and constricting. A problem, whatever its nature, can only come into existence when forward momentum in a particular situation has been stopped. Now, the statement or appraisal of just what it is in the situation that calls out the inhibiting reactions is what we call gathering the data or facts by analyzing the situation. The hypothesis is merely a mental reconstruction of the situation, taking into account its presumed unusual aspects, and designed to eliminate what was previously inhibiting (11). The hypothesis serves to

unplug the situation, with the facts duly taken note of, so that forward action can continue. The problem is solved when the forward momentum resumes. In other words—and this is important—the unplugging of the situation depends initially on the problem being resolved *in the mind* of the hypothesizer. External reality gives its assent or dissent to our appraisal of the facts only later on, when we experiment by acting on the hypothesis.

In daily problem-solving as well as exalted scientific method, the process is the same, that of simple inference. The perfection of scientific method as a reality-probing device lies simply in the care and exactness with which the problem is defined, facts gathered, and hypothesis formulated. The experimental verification which caps the process is carefully controlled (12).

PERSONAL VERSUS SOCIAL ROLE-TAKING

Thus, the primary character of thought, for the developing individual as well as for Radin's Winnebago, is its function as a proof of reality. The scientific method is a method of natural inference which grows out of a more primitive "attitude taking." To get a proper appraisal of a social situation in order to act, the individual tries to get as many perspectives as he can on the situation, so that his behavior will be based on sound inference. It is to the great merit of the sociologists to have insisted that the simple operation of role-taking is integral to social living: role-taking simply means taking the attitude of others toward oneself and toward the objective situation, so that behavior will be based on a many-sided pattern of inferred facts. Role-taking is an anticipation of the situation for valid action. It is because everyone has roles and can imagine the roles of others, that social behavior is at all possible with a minimum of confusion. Role-taking, in sum, is a fundamental source of data obtained by the trial-and-error method practiced within the individual by thought. It is a natural means of providing information by inference. Ultimately, then, we can see that the individual is *forced to become social in order to function*: his behavior cannot take place independently of thoughtful

identification with the behavior of others, i.e., role-taking.

ROLE-TAKING SKILL AND MENTAL HEALTH

Norman Cameron has beautifully demonstrated that some forms of behavioral dysfunction, especially paranoia, arise through the individual's inability to take roles (13). Thus, instead of constantly validating his action and thought by sound social inference, he comes to create a purely private delusion; at no points in this delusion do the real attitudes and roles of others break through. The individual has effectively isolated himself, and has determined his own eventual destruction, by his inability to see himself and the social situation from a many-faceted view.

Role-taking skill can, in fact, be considered a pivotal criterion for mental health. In his ability to take roles, the individual allows himself a flexibility, an adaptability and re-adaptability that makes for a constantly buoyant orientation to a changing social field. An individual who cannot take roles, risks submerging himself in unverifiable private thoughts and delusions, as his suspicions and susceptibilities are reinforced into a false dogma, which is unquestioningly adhered to. In his inability to throw fresh social light upon his private preoccupations, by taking the role of others, the paranoid becomes a dogmatist. His theory (delusion) was initially a mental release from an intolerably uncertain situation, but he becomes hedged in by the dogma itself.² Now paranoia is a very graphic illustration of how social isolation is effected by the inability to use thought

² Cf. Boverman's suggestions on the therapy of paranoiacs (14). He points out that the therapist should be honest with the patient, make it known that he considers him ill, and not humor him. In other words, the therapist should very early attempt to undermine the false theory, by injecting into it some incompatible facts. It would seem that confronting the patient with the therapist's reality serves to attack the paranoiac inference before it can luxuriate. Before, in other words, it can accomplish what it sets out to do, which is to create an unplugging of the situation. The therapist then becomes a contact in reality, for which the patient must forfeit in part his false inference. His inhibition would thus increase, creating motivation for a therapeutic cure.

properly in reality-testing. The main function of natural scientific inference is thereby defeated. We are tempted, therefore, to support the view that here, indeed, is an objective criterion for pathological behavior. The question is prompted :

Can the idea of mental health be considered a phenomenon purely relative to cultural norms, when role-taking skill defines the individual's flexibility and adaptability, and therefore his sound social functioning ?

It would seem that objective criteria for social man do exist. But we have not yet examined the crucial dichotomy of preliterate social versus postliterate private thinking.

SOCIAL PHILOSOPHY AND THE IDEA OF "EMERGENCE"

George Herbert Mead formulated a brilliant philosophy of social man which culminated in a challenging hypothesis : that mind is an evolution in nature, and that sociality gives form to emergent mind. Mind, in other words, is first formed in the infant's taking the role of others to orient his own action by natural inference. So that, evolved on its highest level, consciousness is wholly socially reflexive : the individual apprehends as wide a variety of generalized standpoints as possible. By taking the role of the other in thought, the mind can be projected to any part of the universe ; the man from Mars enters our thinking to examine us critically. Meaning in life is fashioned from the perspectives which thought can encompass. Beginning as painful inference to overcome physiological helplessness, the infant's mind becomes, ultimately, an impersonal, socially reflexive entity, projecting disembodied scientific concepts. Through impersonal rational mind, man becomes wholly social.

But he does not become *personally* social. Here is the rub. Implicit in our discussion of role-taking is the idea that it may serve two kinds of thought processes : 1. That process whereby the individual assumes the attitudes of others, inferentially, in a social situation ; 2. That process whereby the individual makes various inferences in systematized abstract thinking. In order for science and logic to luxuriate, literacy and symbolic manipulations had to succeed

a constricting illiteracy, so that the dexterity of mind in inferring complementary propositions could be given free rein.³ The consequences of this for the individual may now be considered ominous. Role-taking in science and logic, the rapid leafing-through mentally of complementary and opposing attitudes, releases the mind from inhibition. But in his juggling of abstract symbols, the individual formulates problems and hypotheses that have no relationship to present, external reality. The impasse which one reaches in a private, logical problem is an introverted one, it does not need social proving out. When literacy enabled the rise of science, man could proceed to unbridled use of role-taking in inferential logical analysis independent of his own organismic experience. Mind, in other words, loses its primary social function, as it becomes peopled with systems of visual abstract symbols. Logic becomes internally uninhibiting, and the social proving out of the most esoteric products of mind is totally unnecessary. Einsteinian generations of thinkers could live a part of each day taking the role of light beams around the sun, and thus be truly lost to the social community a good part of the time.

Emergent mind seems to operate with a vengeance against the animal's boundness to the here and now. When the "superego" is implanted in the child, his mind is claimed for society. Paradoxically, the further development of rational thought serves to separate the individual more and more from his early symbolic identifications, whether as the growth of the scientific thinker or the religious convert. The self-custodial function of the superego runs its full course : as rational scientific mind becomes thoroughly social, the *individual* is given the possibility of becoming asocial. The written word and the development of logic serve to free man from a personal dependence upon the immediate social world.

PUBLIC VERSUS PRIVATE LOGIC

Despite the abstract level of our discussion thus far, its import to a practical psy-

³ This does not imply any absence of abstract inferential skill on a preliterate level—only that in the absence of literacy symbolic dexterity is seriously hampered.

chiatry is quite clear. As private logic enables the luxuriation of a symbolic world that is idiosyncratic, the individual is allowed to create a psychological behavioral world as fantastic as that of the legendary "primitive." In other words, though we should like to imagine that the growth of literacy has permitted an unprecedented realism, we may be as far from it, individually, as ever—and perhaps even a good deal further. If the separation of public and private logic represents a growing historical dichotomy, the subjective and objective worlds are no nearer to determination by realistic standards.

Margaret Mead once observed, that in our culture cause and effect thinking is *culturally-learned*. Quite naturally, we link present happenings to past causes, even if thereby we really learn or explain nothing: The psychiatrist is best witness to the patient who painstakingly links present malfunction to minute sexual trauma of the past, when in reality these have nothing to do with his basic problem. Furthermore, although we culturally value the idea of realism, the testing and proving-out of propositions, it might be found that we are quite off the mark in most of our thinking. At the present point in history, it would probably take a visitor from an uncorrupted planet to discover the illogic in our minute checking out of the mechanical details in a new car, which we may have never needed yearly-renewed in the first place.

Hallowell has well presented the main function of culture for the human animal (15). Culture provides the self-reflexive human with a psychological behavioral world designed to furnish him with the one premise without which he cannot live: the conviction that he is an object of primary value in a world of objects. Culture, in brief, provides the symbolic myth of meaning to an otherwise impossible world. Since man is the only animal who can reflect, who can objectify himself, he is thus also the only one who must infuse his self-objectification with a sense of primary value. This basic function of culture is well-known and unassailable. It follows, of course, that if each individual must assign himself a sphere of primary value in a psychological behavioral world, each society

tends to arrogate unto itself the pretension to a symbolic meaning system that is unimpeachable—if it is at all approachable by others. Ethnocentrism is not a historically conditioned habit of thought, or a laxness in logic, it is a condition of self-referential existence. It is, therefore, only natural that our 20th century society should pride itself on the attainment of the highest realism possible, and thus consider itself to culminate a long tradition of historical striving.

THE FREEDOM TO DIE AND THE COMPULSION TO CONFORM

But there are at least two very trenchant reasons for doubting that widespread realism is characteristic of our culture. In the first place, as indicated above, the private world of the literate thinker may never be socially proven-out. The logical manipulations of the scientific theorist may provide both himself and a good percentage of his fellows with a full time activity that may only be proven *totally unreal* several generations later. Not only does the individual's private logic permit him a socially-accepted positive self-valuation on the basis of his "scientific genius," but his real alienation from the world of reality can, like paranoia, proceed without check. In the second place—and this is really the crux of the matter—this alienation *has nothing to do with survival in an immediate sense*.

Radin's Winnebago could afford to be tolerant of the individual's deviation by private thoughts. Besides, where community survival hinges on some sound everyday logic in hunting and fishing, and everyone usually pitches in in the task, social testing of individual preoccupations is never long delayed. Shared activities upon which life and death depend are more immediate, they demand a more strict adherence to logical rules that can be perceived by all. The individual who demonstrates subjective deviation or nonsense in the dangerously exacting job of off-shore communal fishing will often be quickly dispatched into unconsciousness by an alert group.

In civilized living, on the other hand, survival just "happens" in the midst of confusingly plural activities. For most, the essentials of life are "born packaged," and the sight of animal slaughter sickens. With

social survival assured in a society of plenty, and with the products of private logic susceptible of remaining untested during an entire lifetime, the individual can no longer destroy himself, like Radin's Winnebago.

Thus, our society is unique in that, not only is the individual immune to self-destruction by following his private logic, but even were he to follow it to the point of extreme catatonia, *we do not let him die*. Our society places a positive value on neonates, aged and maladjusted that in itself might be considered culturally and historically somewhat peculiar. (One has only to compare the treatment of the old and infirm among the Eskimo and certain African tribes; the neonate cannibalism among the Australian aborigines; and the alacrity with which the natives brought their mentally ill to the first Madagascar mental hospital opened by the French—they no longer had to kill them.)

The primitive, in other words, tolerates the aberrant private logic because he also tolerates the self-destruction which it entails. By the very same cause and effect, we do not tolerate the self-destruction, and therefore *do not tolerate the private world view*. Carstairs observed that to the extent that private logic is considered dangerous to a society, it will be controlled. In those instances in which magical thoughts are a menace to the whole community, the individual's own death may be unimportant, but the damage he can do with his mind is. Thus, in this sense, we are just as restrictive of individual freedom as is the primitive, and perhaps more so. We have not improved on the formula, but only coined a peculiar cultural version of it: having saved the individual from death, we have also to take the next logical step, which is to bring his thinking into line with that of the rest of society.⁴

⁴ Recent class studies of mental health show sharp discrepancies that seem to support the primitive-modern dichotomy outlined above. In social class 5, where survival is always more or less at stake, "mental health" is almost uniquely an empirical, objectively determinable phenomenon: is performance of the breadwinner adequate to assure family survival, despite the most personal of idiosyncracies? In class 1, on the other hand, where survival is largely assured, a close interpersonal and personal check is kept on social function-

The ineluctable historical innovation of literacy, private logic and an economy of plenty seem to exacerbate the problem of mental health. To what extent can we clarify, by attempting to view objectively the peculiar rationalizations of our culture as it copes with these innovations? This is a research problem of no small import. For example, a lobotomy not only prevents individual "death," it also prevents cultural death. The primitive, by allowing his deviant to die, forestalled thereby any living reproof to the sacrosanct symbolico-cultural system of sustained meaning upon which society depended. The cultural myth of action and meaning *had to be* unshakable, since deviation from it demonstrably meant death. But the living mental deviant in our society permits no such ready reinforcement. Allowed to live, his private distorted meanings assume an unnatural discordancy; they threaten to illuminate the transparency of the culturally-fabricated meaning from which humans draw sustenance. We can rejoice when the disease-ridden patient triumphs over natural biological limitations. But it is quite otherwise with culture: man cannot allow triumph over or indifference to his own fabrications of meaning.

HUNGER AND SATIETY ¹

ALBERT STUNKARD, M.D. ²

Recent physiological discoveries have outmoded what is still the prevailing clinical theory of hunger. This paper describes these discoveries and considers their implications for our understanding of overeating. First, however, let us examine our current theory of hunger.

A "PERIPHERAL" THEORY OF HUNGER

The physiology underlying the hunger drive had been a subject of speculation for 100 years when the observations of Cannon (1) and Carlson(2) at the beginning of the century gave rise to the first empirically based theory of hunger. While studying the gastric motility of human subjects, Cannon in 1912 discovered that hunger pangs coincided with powerful contractions of the empty stomach. Hunger—both as a sensation and as a drive—was thereupon referred to these gastric "hunger" contractions and they were ascribed a primary role in the regulation of food intake. In this view, a state of nutritional depletion was the stimulus to the gastric contractions and the discomfort of these contractions motivated food-seeking behavior. This resulted in the ingestion of food which restored the depleted nutritional state and so removed the stimulus to the gastric contractions. Without these contractions there was no longer an impetus for food-seeking behavior.

This theory adequately described the known facts and it served for many years as the standard explanation of hunger. Such success was no doubt partly due to the high prestige of peripheral drive theories, of which this theory of hunger was a most respectable member. The essence of these theories was that they located the origin of drives in peripheral structures such as the stomach (hunger), the throat (thirst) and the genitals (mature sexual behavior).

¹ This work was supported in part by a grant from the National Institute of Mental Health, National Institutes of Health, U. S. Public Health Service.

² From the Departments of Psychiatry and Medicine, University of Pennsylvania, Philadelphia, Pa.

One of the finest analyses of peripheral drive theories, that of Freud's 1916 paper on "Instincts³ and their Vicissitudes"(3), is summarized schematically in Figure 1.

FIGURE 1

Schematic Summary of the Peripheral Theory of Hunger Described in the Text

He defined the "source" of the drive as "that somatic process in an organ or part of the body from which there results a stimulus (which is) represented in mental life by an instinct." The "source" gives rise to behavior called the "aim" which "seeks to abolish the condition of stimulation in the source of the instinct." This "aim" is achieved through the final term in the equation,—the "object"—, a person or thing which is defined as "that in or through which the drive can achieve its aim." This analysis reveals how similar the peripheral theory of hunger is to Freud's most enduring theory of drives. His model is just as appropriate for dealing with behavior believed to have its origin in the stomach as for that with sources attributed to the oral, anal and genital regions.

To summarize peripheral drive theories: a disequilibrium in the internal milieu activates a peripheral structure which in turn

³ In this translation the German *Trieb* (drive) has been rendered as instinct.

triggers off behavior designed to restore the internal milieu. Once this restoration is achieved the peripheral organ stops sending out stimuli and the drive runs out of steam. To anticipate the new developments in drive theory we should note that in the peripheral theories satiation is simply an incidental aspect of a drive. It is no more than what happens when a drive runs out of steam.

A "CENTRAL" THEORY OF HUNGER

Two lines of investigation sounded the death knell of the peripheral theories of hunger. One discovered events which could not be explained by a peripheral theory and the other uncovered evidence for a central theory.

Grossman showed that denervation of the human stomach did not abolish either the sensation of hunger or the ability to regulate food intake and that animals were perfectly capable of regulating food intake following gastric denervation (4, 5). Furthermore, the removal of the entire stomach in man does not abolish hunger sensations and such individuals can regulate food intake (6). In the face of such evidence it is hardly possible to accord to the stomach the vital role assigned it by peripheral theories.

The decline of the peripheral theory of hunger has been hastened by a series of remarkable physiological discoveries. The reticular activating system and the limbic system, structures with enormous potential for our understanding of behavior, have been extensively investigated. And of even greater significance for our understanding of hunger has been research on the hypothalamus. Here, in an area no larger than 2 cubic centimeters, have been discovered neural centers which control such diverse activities as feeding, drinking, respiration, sleep, emotionality and sexual and maternal behavior. These centers are sensitive to a wide variety of influences; indeed, every influence which has been implicated in the motivation of behavior affects hypothalamic centers—peripheral sensations, higher nervous activity, hormones and changes in the internal milieu. This striking localization of sensory and motor functions strongly suggests that the integrating mechanism for motivated behavior lies in the hypothal-

amus. Here, rather than in peripheral structures, the determinants of drives are registered and processed, and goal-directed behavior is instituted. This vital role of the hypothalamus makes its characteristics of profound importance for our understanding of behavior. One characteristic of its neural organization is particularly relevant to the hunger drive. The hypothalamic centers mediating hunger consists of not 1, but 2 pairs of nuclei,—one for initiating and one for inhibiting feeding behavior. Why this division of labor?

Stellar has summarized current views in his proposition that the "arousal of motivated behavior is determined directly by the output of the excitatory mechanism and the satiation of motivated behavior by the output of the inhibitory mechanism" (7). And judging by their relative sizes the inhibitory mechanism is fully as important as the excitatory. Now this is a remarkable notion! Our behavioral analyses have long viewed satiation as a purely incidental aspect of the drive—what happened when the drive ran out of steam. But if satiation were merely such an epiphenomenon, why should it need such a powerful neural apparatus? Clearly this anatomical fact forces us to reconsider the nature of satiety.

THE NATURE OF SATIETY

It is easier to find a rationale for known structures than to deduce such functions before the structures are known; and any effort to find a rationale for a dual control system for feeding behavior is just such a *post hoc* exercise. Nevertheless, the time relations of eating and satiety,—and particularly the lag between satiety and repletion of the internal milieu—strongly suggest that some such control is necessary. Eating stops considerably before the internal milieu is restored to the conditions which were present at the time the drive was activated. Indeed, if eating terminated only when the internal milieu had been restored to equilibrium, any food still in the gastro-intestinal tract, often a considerable amount, would produce an overshoot in caloric repletion. Accordingly, in defining satiation, it is necessary to add to traditional drive theory a time-delay function which shuts off eating at a time prior to the complete restora-

tion of caloric equilibrium.

Communications engineers have found that a time-delay function can be introduced into an automatic regulatory system by a single sensing device, provided that the system functions under rigidly controlled circumstances. To maintain stability under circumstances as variable as those of feeding behavior, however, 2 sensing devices are necessary, one for stopping as well as one for starting eating. The requirements of automatic control, thus, provide our sought-for rationale for the importance of satiety.

This increased importance of satiety is illustrated in Figure 2, where we see that

FIGURE 2

Schematic Summary of the Central Theory of Hunger Described in the Text

satiety has been removed from its implicit position in the source of the drive and has been added as another term to the equation. What is the effect of this reformulation upon our understanding of obesity? Its greatest effect is to free us from a major constraint of the older theory and to give us more freedom in explaining behavior. For example, we are no longer forced to explain all overeating as a manifestation of an increased hunger drive. Increased activity of the feeding centers may, indeed, produce overeating. But it could also result from a decreased activity of the satiety centers; and these 2 forms of overeating may differ dramatically. These possibilities will be illustrated with examples from animal and clinical studies.

ANIMAL STUDIES

Experimental work has shown that eating

behavior may vary greatly depending upon the conditions which initiate it. The traditional method utilizes food deprivation. After a period of food deprivation an experimental animal will not only eat a large amount of food but, when obstructions are put in the way of his obtaining this food, he will work to overcome the obstructions. This sequence is so consistent that the duration of food deprivation can serve as a measure of the strength of the drive. This relationship holds whether drive is measured in terms of how much food the animal eats, how heavy a cover to the food dish he will lift or how much electric shock he will take to reach the food.

This equating of duration of food deprivation and strength of drive had been so firmly established that we were quite unprepared for the paradox introduced by Miller, Bailey and Stevenson in their paper on "Decreased 'Hunger' but Increased Food Intake in Hypothalamic Obese Rats." These authors showed that destruction of the hypothalamic centers mediating satiety resulted in a peculiar form of overeating. As long as food was freely available, the animals overate. However, as soon as any obstruction was placed in the way of their eating,—as soon as they had to work for food,—they simply sat down on the job. Thus, by any of the traditional measures of drive strength the rats were not hungry; but, when provided free access to food, they overate. This phenomenon poses a formidable explanatory problem to traditional drive theory; it is a logical consequence of the view that overeating can result from a failure of satiety.

CLINICAL STUDIES

Normal eating behavior in man is subject to conditions remarkably similar to those existing in the lower animals. In both man and animal the strength of the hunger drive depends almost exclusively upon the duration of food deprivation. After eating, drive level is low and it increases with increasing deprivation. In the animal this increase is measured by determining how much it eats and by how hard it will work to get food. These measures can be used in man, and, in addition, man's vast repertoire of response permits us to measure the effects

of food deprivation upon many other forms of behavior. Several studies show that food deprivation produces consistent effects upon perception, fantasy and overt behavior. The per cent of food images in ambiguous pictures, for example, increases with food deprivation(9). Under such circumstances there is an increase in certain food-related fantasies evoked by Thematic Apperception Test cards(10). Finally, increasing food deprivation produces an increased tendency toward social affiliation(11).

Abnormal eating behavior in man does not exhibit these comfortable regularities and our conceptual tools have been limited by the constraints of traditional drive theory. We have today only one explanation as to how neurosis can produce overeating: drives which cannot otherwise achieve outlet take over the channels of discharge of the hunger drive. This drive-displacement theory of overeating has for years been the assumption of most clinical literature on obesity.

What of the alternative? Is there any virtue in looking at disturbed eating behavior from the point of view of satiety as well as of hunger? Do we find any examples which might be attributed to a failure of satiation as distinguished from an increase in hunger drive? The answer is yes! Many obese patients describe their overeating in terms far more appropriate to a failure of satiety than to an increase in drive. How rarely do even intensely neurotic obese persons tell of an irresistible compulsion to eat large amounts of food! And how frequently does the exasperated housewife tell of her inability to stop nibbling once she has begun! The distinction between increased hunger drive and impaired satiability becomes even more marked in the small number of obese persons who eat in abnormal stereotyped patterns.

This distinction recently led to a fruitful reappraisal of an obese man who had long been considered a "compulsive eater." The patient's overeating had begun abruptly following a bout of encephalitis at the age of 12, and it had been present ever since, not apparently affected by changes in his life situation. This seemed unusual if his overeating were indeed compulsive, and investigation raised further doubts about the

diagnosis. He said that he did not feel any compulsive quality to his overeating. Indeed, he never felt any strong urge to eat, and he was perfectly content to forego food for periods of as long as 18 hours during experimental studies which claimed his attention. His overeating afforded none of the relief of tension which might be expected to follow the performance of a compulsive ritual, nor did it arouse any apparent guilt. Instead, he attributed his overeating to a disinclination to stop eating as long as food was available. In short, this man, who had suffered extensive brain damage, ate very much like a rat with experimental damage to its hypothalamic satiety centers. It seemed entirely possible that this man overate for the same reasons.

A more common clinical picture characterized by an inability to stop eating is the "night-eating syndrome"(12). Persons with this distinctive eating pattern are anorexic during the morning and may eat little or nothing before noon. By supper, however, they have begun to eat heavily, and they continue all evening, often until late at night. When asked to describe their feelings during such periods these persons rarely speak of being hungry, and many of them even volunteer that they are not overeating because of hunger. They report, rather, that they frequently find themselves "nibbling" and just can't seem to stop. It is noteworthy that if they cannot begin eating they rarely develop any strong desires to eat or make any great effort to obtain food. Even when they are severely agitated, there is none of the goal-directed urgency of the addict deprived of his narcotic or the alcoholic at the outset of a binge.

There is no reason to believe that the night-eating syndrome results from any irreversible damage to the hypothalamic satiety centers. It seems, rather, a reaction pattern which occurs during periods of life stress and which disappears with relief of that stress. Its characteristics, however, suggest a functional impairment of the satiety apparatus.

Once we can describe overeating *not* based on an increased hunger drive, overeating which *is* based on an increased hunger drive becomes a meaningful idea. Viewed in this critical manner, one form

of overeating definitely seems to result from an increased hunger drive. A small number of obese persons overeat in a pattern which we have called "binge-eating" (13). Such eating often has an orgiastic quality and enormous amounts of food may be consumed in relatively short periods. In contrast to most obese persons, binge eaters *do* report an irresistible compulsion to overeat and their descriptions are concerned far more with the intensity of their need to eat than with any inability to stop eating. Eating binges often begin with explosive onset and are usually followed by periods of remorse and self-condemnation. Although binge-eaters emphasize the mysterious "out of the blue" quality of their binges, acquaintance with their life situations reveals that the binges occur during periods of life stress. They are particularly common during depressive reactions, and, in contrast to other forms of overeating, appear to have highly personalized unconscious meanings.

WHAT OF THE FUTURE ?

Where do these ideas lead? The way seems clear. If overeating can indeed result from either an increase in drive or a decrease in satiability, this difference should be experimentally demonstrable. We have described methods for measuring increased drive. How impaired satiation could be demonstrated in a clinical setting is less clear, but an effort to develop methods to test a potentially fruitful theory could be a welcome change from our current all-too-sterile empiricism. Once such methods are available, there are a great many questions to ask :

Can obese persons be distinguished from non-obese persons and from each other by their tendency to show an increased drive or a decreased satiability? Does either pattern become intensified during periods of stress? Is there any connection between a pattern and biochemical or personality variables? Can the patterns be experimentally manipulated? And, ultimately, how can this information help our patients?

NEUROLOGY AND "NEUROLOGIZING"

In his delightful essay on "Drives and the C.N.S. (Conceptual Nervous System)"

Hebb (14) pointed out that, despite even determined attempts to escape "neurologizing," most psychological theories are influenced by our conceptions of the central nervous system. He therefore proposed that "if we must neurologize, let us use the best brand of neurology that we can find." Hebb's plea to his academic colleagues can be even more appropriately addressed to psychiatrists, for psychiatric theories have been influenced at least as much by neurologizing as have been those of academic psychology. Indeed, if we confine our attention to the history of drive theory, the parallels between academic psychology and medical psychology are striking.

During the first years of the century academic psychology was as strongly influenced by the instinct theories of MacDougall as was medical psychology-to-be by Freud's libido theory. The attempt to apply these theories in a systematic manner, however, gradually revealed their various deficiencies. In academic psychology the result was the radical repudiation of drive theory and the rise of behaviorism with its emphasis on immediately observable events. In psychiatry, the first reaction to the growing awareness of the deficiencies of drive theory was revisionism rather than revolt, and Freud left his libido theory standing uneasily beside the new ego psychology to which he increasingly devoted his attention. But this shift in emphasis only deferred the behavioristic assault. Although it came long after similar developments in academic psychology, and was never so methodologically rigorous, Sullivan's theory of interpersonal relations may be viewed as a behavioristic critique of psychoanalysis and particularly of its theory of drives. For Sullivan's goal was a shift of emphasis from the "mental apparatus" which had been Freud's concern to the immediately observable interpersonal events of the therapeutic situation.

There is no need to labor the benefits of behaviorism in obviating unnecessary assumptions, exposing useless constructs and in general tidying up our conceptual apparatus. Academic psychology and psychiatry have gained too much from this latter-day Occam's razor ever to long for a return of the good old days of transmutable drives and ambiguous energies. Nevertheless neu-

rophysiology is providing us with information so obviously relevant to behavior that it can hardly be ignored. If, instead of merely tolerating these new findings, we set to work to use them to construct new and better theories about drives, a great deal of exciting material lies at hand. And we could proceed with the comforting knowledge, not always available to our forebears, that these theories could be anchored to hard facts and tested at all kinds of convenient places. Already physiological psychologists have seen the possibilities and are applying these notions to their work on animals. Can clinicians afford to tarry?

SUMMARY

New physiological discoveries are providing the behavioral sciences with a unique opportunity for the reconstruction of traditional theories of motivation. We are no longer constrained, for example, to view overeating solely as a result of an increased hunger drive. This apparent contradiction results from the demonstration that the hypothalamic centers mediating hunger and satiety have separate anatomical localizations and separable behavioral consequences. Overeating can thus theoretically result either from an increase in hunger drive or from an decrease in satiability. The first possibility has generally been accepted with little question. The second has now been demonstrated by experimental damage to the satiety centers of animals who thereupon present the paradox of an animal which eats itself into obesity through a hunger drive which is actually reduced in intensity. Recent clinical studies suggest

that either decreased satiability or increased drive may occur in human obesity. Persons manifesting the "night-eating syndrome" report an inability to stop eating rather than any increased desire to eat. Obese persons who overeat in binges, on the other hand, report compelling urges to overeat at such times.

HORACE AND MENTAL HEALTH

SISTER EMILY JOSEPH, C.S.J.¹

One has not to search far among the personalities of classical times to find a reliable exponent of the principles of mental health. The life lived by Quintus Horatius Flaccus and the guides he proposed for happy living might well serve as material for a modern textbook entitled *Principles of Mental Hygiene*.

Authorities in this field of mental health are hesitant to say that psychological disturbance and the various aspects of mental disorders which today's psychiatrists have diagnosed and classified are more prevalent in our modern world than they were in days gone by. This much can be said: the formal awareness of emotional problems is one of the characteristics of our age. Furthermore, the specialists are ready to itemize the personality factors that characterize the mentally healthy person. In capsule form the mentally healthy person may be described as: 1. One who feels comfortable about himself; 2. One who feels right about other people; 3. One who can meet life's demands.

The mental hygienist, attempting to elaborate upon each of these points, constantly strikes chords, iterates themes which bring a smile to the lips of the admirer of Horace. Why not invite the poet from Apulia, *ex humili potens*, to speak in person upon this topic and, by suggestions and illustrations from his own life, expound the principles that make for emotional stability and mental adjustment? Perhaps this sophisticated 20th century can still glean something from the wisdom of the past.

With a gracious smile Horace responds to the invitation, mounts the rostrum, and assumes the role of clinical psychologist. A relieved expression appears on the faces of the psychologists in his audience as Horace prefaces his lecture, in his own simple and unforgettable manner, with one of their own fundamental principles: "You are not simply body without a heart!" (1)

Horace first approaches the idea that the mentally healthy person is one who feels

comfortable about himself. He draws upon scenes from Homer to indicate that one must not be mastered by one's emotions, whether they be fear, anger, envy, distrust, or any others. Paris, he implies, was mad, refusing obstinately to give up Helen even to enjoy personal safety, a kingdom, and a life of happiness (2). Next he cites Achilles and Agamemnon, childishly squabbling for their war prize. In their case, too, the trouble evolved from uncontrolled emotions (3). Invariably, the poet observes, those who let their emotions get beyond their control bring suffering to those closest to them (4).

Avarice and greed are, in Horace's estimate, a positive form of mental illness. He actually says so, and declares that the possession of estates and unlimited wealth cannot relieve the fever that torments the sufferer, for: "You're not taking care of the emotion!" (5). Anger, too, must be controlled: "Anger is temporary insanity; control this emotion!" (6). As for the mental torture induced by the passions of jealousy or envy, Horace declares that it exceeds all physical tortures that can be conceived (7). Ambition, too, on the part of one not fitted for the position to which he aspires is, in Horace's eyes, another manifestation of poor self-adjustment. The path of such a one will be strewn with unpleasantness and possible frustration (8). With a wry smile that implies "present company excepted," Horace adds a final observation on this point: "Select anyone at all from amid a crowd: his craving for money or for paltry popularity makes him a sick man" (9).

Once such passions and emotions are set in order, mental health is, to some extent at least, secured: "Let the soul find joy in the present moment and disdain to worry about what lies ahead and let it season the bitter things of life with a quiet smile" (10). Having learned the therapeutic powers of a bit of gentle laughter when things go contrary to his expectations or desires, the well-adjusted person, far from succumbing to frustration, shrugs his shoulders with the observation: "Nothing is in every respect perfect!" (11).

¹ College of St. Rose, Albany, N. Y.

The proof that such a reaction is not cynicism, Horace would insist, lies in the individual's ability to laugh at himself. This Horace shows that he could do in the amusing and exaggerated description of his own helpless state of victimhood as he is first caught, then tortured, by the garrulous and insistent *persona non grata* who accosted him one sunny morning along the Via Sacra (12). It is to provide a laugh at his own expense that he elsewhere draws the sorry picture of himself, a man in his mid-twenties, stammering in boyish embarrassment as he presented himself for an interview with the mighty Maecenas (13).

Horace would be the first to admit, with the psychiatrists, that everyone has certain basic needs. Unless these are satisfied, the emotional life of the individual is disturbed, with results which range in seriousness from the trivial to the extremely grave. Foremost among these needs is the desire for acceptance and security. Horace recalls that, returning to Rome after the Battle of Philippi, he faced a crucial period of transition in which he might easily have become the victim of a set of circumstances disruptive of his emotional stability. His father was dead; he was without friends, or funds, or job, in the Capitol; his military service had been with the defeated troops. How warped one's personality can become and how prone one is to manifest hostility when one suffers from deprivation of a basic need is evidenced by the cynical, embittered tone of his earliest poetic attempts, composed during the leisure hours provided by an insignificant and uninteresting job as a quaestor's clerk.

Fortunately, two young poets of the day manifested an interest in the unknown but promising author of the cynical verses and recommended him to the attention of one of the foremost citizens of the day, the wealthy patron of the arts and Augustus' friend and adviser—Maecenas (14). Horace's loneliness, disillusionment, and discouragement were dispelled when Maecenas invited him to join his social and literary coterie.

Horace next remarks that a mentally healthy person neither overestimates nor underrates his own abilities. Pointing to passages in his writings, he indicates his awareness of his own limitations: he gave up attempts to write verses in Greek (15),

refused to attempt epic poetry (16), and spoke modestly of the talents that were his (17). He even refused to lay claim to the title of "poet" at the time when he was writing his earlier satires (18), but acknowledges that in his later efforts—his Odes—there are present the 3 elements which he prescribes as requisites for great poetry, *viz.*, natural talent, inspiration, and the ability to utter noble thoughts (19).

A favorite passage eloquently indicates that he has achieved the success he desired and finds his need for security satisfied:

I have completed a monument more enduring than bronze and loftier than the royal pile of the pyramids, one which the wasting rain, the furious North Wind cannot destroy—no, nor a countless series of years nor the flight of ages. Not all of me shall die (20)!

Even more indicative of sound mental health, says Horace, is the ability to derive satisfaction from the simple pleasures of everyday life (21). With senseless extravagance many wealthy Romans of Horace's day were rearing sumptuous palaces and vulgarly displaying their wealth (22). In contrast to their restless, anxious, grasping avidity is the quiet delight that he finds in Maecenas' precious gift of the Sabine Farm (23). Only contentment with one's humble lot can bring peace of soul (24). Why, he asks, should he exchange his home in the hills for some luxurious, modern dwelling whose attractions will probably allure thieves—or raise his taxes (25)?

Horace points out that most men fail to find happiness in life and consequently suffer from various degrees of maladjustment simply because they cannot rest content with their lot in life (26). Not that he forbids one to devote his energies to self-improvement! Far from that! "There is measure in all things," he says (27); but, he concludes, it is the rare thing to strike this happy mean; consequently, those who have lived well-adjusted lives are in the minority (28).

At this point Horace interrupts his lecture to draw some papers from a briefcase. He begins to read: "Once upon a time, the story goes, a country mouse welcomed a city mouse in his poor hole, host and guest

alike being old friends"(29). The passage is lengthy—a delightfully vivid, Disneylike characterization of a sophisticated little city mouse who visits his old friend, a thrifty, hard-working country mouse, and prevails upon the latter to give up his toilsome life for the affluence and ease of the city. "At best," he tells his country friend, "life is short; you may as well get all the joy out of it that you can"(30)!

The advice seems sound; the host acquiesces; together the tiny friends scamper beneath the protecting shadows of the city walls and enter a luxurious dwelling. In the banquet hall are strewn the remains of a sumptuous feast. Now it is for the city mouse to play the role of host and he energetically sets about serving his guest the most tempting morsels. A sudden disturbance tumbles the two intruders from the elegant dining-couch as the terrifying barks of Molossian watchdogs and the clanging of folding doors give warning of the approach of some of the household. Quoting the final observation of the shrewd little country mouse, Horace concludes his recommendations about learning to derive satisfaction from the simple pleasures of life: "Then says the rustic: 'I have no use for such a life, and so farewell: my hole in the woods, secure from dangers, will console me along with my homely vetch'"(31).

Horace pauses, reaches for a glass of Falernian which someone has set conveniently near, relishes a sip of it, and continues: "The mentally healthy person is one who feels right about other people. I offer you a working principle: Not a soul comes into this world devoid of faults. The best is he who is loaded down with the least of them . . . One who expects his friend not to be offended by his own warts will pardon the other's pimples. It is but fair that one who asks indulgence for *his* faults should grant it in return"(32). He recommends that a tolerant, or even a kindly indulgent attitude be adopted in social relations. Emotional disturbance invariably results from poor social adjustment. In the case of the well-adjusted individual, his positive emotions are dominant. Love, particularly, contributes to his personality development, to a wholesome mental outlook, to a happy, well-adjusted life.

Horace selects a number of situations met in ordinary living to illustrate his point. He describes the tendency of a father or lover to overlook the faults of the loved one, for "love is blind"(33). Does not a father give such nicknames as "Chick" or "PeeWee" or "Stretch" to sons with physical peculiarities? A son's stinginess the indulgent father calls thriftiness; his quarrelsomeness gets the name frankness; his wily ways the father deems shrewdness(34). This tolerance must extend to all age groups. As a middle-aged bachelor, Horace remarks, he did not find it too difficult—although some do—to be understanding of the amorous and flirtatious inclinations of adolescents. In fact, he encourages them, for, he reminds his listeners, "You're only young once!"(35)

Underlying the entire pattern of one's healthy adjustment to his fellow men is the need for self-confidence. Early environmental factors contribute in large measure to the degree of self-confidence with which a person adjusts to social situations in later life. By numerous passages selected from his poems, Horace testifies that parental affection shed its warmth over his childhood and adolescent years. In touching lines he pays affectionate tribute to his father, a man of lowly birth and slight income: "Never while I am in my right mind could I be ashamed of such a father!"(36)

The affection of his cherished friends, too, contributed to Horace's self-confidence and thereby to his successful and happy living; for, he says, thinking of Vergil, Maecenas, and many others, "Nothing, so long as I am in my senses, would I compare with the joy a friend may bring"(37).

Horace pauses again as he notes that one of his audience has an inquiry.

"May I ask you, sir, why you never married? In view of the flirtatious tone frequently detected in your odes, I am inclined to think that you found the company of many a young woman delightful. Yet you remained a bachelor, even in spite of Augustus' insistence upon the importance of large families for the rehabilitation of Rome."

"Your point is well made, my friend," Horace replies genially. "The mentally healthy person must feel right about other people, particularly people of the other sex. I find it somewhat difficult to analyze the

circumstances which resulted in my bachelorhood. Certainly it was not any lack of esteem on my part for the nobility of the married state. Let me quote for you a few lines which express my sincere appreciation of the fact that stability and harmony in marriage is a great blessing: "Thrice happy they and even happier whom an unbroken bond unites and whom a love ne'er sundered by embittered quarrels shall not separate before life's final day" (38). Perhaps I may say that in my friends I found adequate satisfaction of my need for affection. Then, too, the tenor of my life was undeviatingly ordered by my complete dedication to literary efforts. This precluded, almost from the years of my early manhood, certain enjoyable but nonetheless distracting associations. You recall my avowal to Maecenas that my sole ambition was to win recognition and renown as Rome's first lyric poet (39). In the achievement of this goal I enjoyed the sense of fulfillment that a man's nature craves and that is satisfied, in the case of most men, by marriage. Thus, my life was free from the blighting element of frustration."

That the mentally healthy person is one who can meet life's demands is the final point that the Roman satirist and lyricist elaborates. Life is filled with difficulties and it requires strenuous effort to surmount them; for, Horace observes wisely, "Life grants nothing to man without much toil" (40). Self-pity has never helped anyone. It is for each one to find out what he can do about his problems and then *do it*. "*Nil desperandum*—Never despair!" warns Horace (41). One must be ready for the ups and downs that must be inevitably met. "The heart that is duly prepared for a change of fortune hopes in the face of misfortunes, grows wary when prosperity is prolonged" (42).

Since attitudes are power houses of psychological activity, the man with a well-balanced outlook on life, willing to face reality, will achieve that all-desirable sign of maturity that can be called the hallmark of the mentally healthy person, namely, emotional stability (43).

"I offer you a motto," Horace smilingly remarks, "if you want to acquire and preserve happiness. *Nil admirari* (44)! Many put too high a value on the material goods

and the honors of this world and allow themselves to become the unhappy victims of disturbing emotions. Make every reasonable effort to improve an unpleasant situation, but at the same time accept the fact that some conditions do not admit of amelioration. In that case the virtue of patience is needed" (45).

Life demands of each individual that as a member of society he assume his responsibilities to his fellow men and willingly utilize his talents or abilities for the good of the group. He must discipline himself to a mode of conduct that begets respect and affection rather than contempt and animosity from his associates. One who fails in this respect, whose self-centered disregard for his neighbor's pleasure is manifested by a disagreeable, non-conformist attitude, deserves the treatment he receives. Typical of those he has in mind, Horace says, is the unaccommodating singer: "All singers have this fault in common: when among friends who request them to sing they can never be persuaded to do so; but when no one asks them, then start and never let up!" (46). This unobliging attitude betrays a selfishness which manifests itself in countless offensive mannerisms.

Indicative of a realistic outlook is the individual's ability to set goals for himself which he can reach and a willingness to make his own decisions. Horace illustrates this from his own situation: Satire, he realized, might win him unpopularity, but he resolved to persevere in writing it, recognizing his limitations in other fields (47).

Calm reflection, an inner debate in which the various courses of action are evaluated, rejected or adopted, must serve as prelude to mature decisions. Reason, not emotion, must rule. Horace assures his audience that he often held such debates within himself (48).

A certain degree of serenity in one's pattern of living contributes valuably to mental poise. Life amid excitement, bustle, and tension of constant activity in Rome Horace found not only irritating but inimical to his concept of the good life (49). "From time to time I had to get away from the city," Horace acknowledges, "and seek relaxation in some such fascinating spot as sunny Tarentum—The corner of the earth that surpasses

all others in the smile it wears'(50). Or, if time would not permit me to journey all the way to the tip of the peninsula, it might be to cool Tibur with its echoing cascade and charming Temple of the Sibyl that I would betake myself, for Rome with its cosmopolitan air I often found uncongenial(51). Unrelieved pressure was unbearable! 'Mingle some moments of levity with your solemn hours of planning; it's fun to indulge in some nonsense on occasion'(52).

The poet pauses for another sip of Falerian.

"A friend, Lollius Maximus, is calling for me in a few minutes. We're going out to my Sabine Farm for the week-end. Just let me quote to you before I leave a prayer I once composed. It outlines my ideal of the happy life. I have found that it takes very little more than this to achieve a healthy adjustment to life and its problems: 'O grant me, child of Latona, I implore, to enjoy what I have and may I be permitted to live out my days sound in body and mind and enjoy an old age that is not devoid of honor nor of love of song I'(53). And now I say to you in parting what I once said to Lollius: Provided Jupiter grants me enough to live on, I shall acquire for myself a well-adjusted mental attitude"(54).

THE CLINICAL EFFECT OF NORETHANDROLONE ON INCONTINENT MENTAL PATIENTS ACTION INDUCED BY NON-VERBAL COMMUNICATION

LUIS SANTOS, M.D., AND MARTIN GROSS, M.D.¹

When engaged in research with chronic psychotic patients in a mental hospital we often ask ourselves whether control experiments are necessary. Here we deal with a presumably stable population, hospitalized for many years, not responsive to treatment. Occasionally one of these patients emerges from a "back ward" and succeeds in leaving the hospital; this is, however, a rare occurrence, especially in patients who have reached deterioration to the point of being incontinent. Over a long period of years the course of such patients is continuously downward; if they improve under some new treatment, we willingly accept a causal relationship and believe that the improvement resulted from such new treatment. Control experiments, we often felt, were necessary to convince others of the reliability of our results; we ourselves were satisfied with the results of our investigation, based on and judged by clinical experience. As one of the present writers (M.G.) expressed it in a panel discussion: "No matched control group is necessary for a study in the setting of a mental hospital, where we deal with chronic psychotic patients who are long-term residents and who are well known to the medical and nursing staff and serve as their own control." We were dead wrong.

In 1958, Vlavianos and Fink(1) described the action of norethandrolone on incontinent mental patients. The potency of this steroid anabolist is experimentally determined by its action on the levator ani of animals. The authors considered logically that this action, if present in humans too, may be of influence on soiling mental patients. They treated 11 male soilers with 30 mg. of norethandrolone daily for 17 to 53 days and found that "8 patients had a positive response with no incontinence from 3 to 7 days after the start of medication" and that 3 remained continent after medication was discontinued. No controls were used. Vais-

berg, Michael, and Saunders(2) followed with a report on 9 patients treated with 30 mg. of norethandrolone daily for 3 weeks. Their results were similarly encouraging. One patient became continent and remained so even after the drug was discontinued; 6 improved markedly. "The patients served as their own controls—all of them having had these symptoms consistently for a minimum of 1 year(5)."

Soiling is one of the great problems in mental hospitals. In one of our wards with 65 deteriorated patients, 75-80% are constant soilers. This ward uses about 550 bed sheets per day. The added attention these patients receive necessarily is best expressed by the attendant-patient ratio which is 1 : 5.3 in this cottage as compared to an average of 1 : 9.2 in the rest of the continued treatment group. We were, therefore, interested to find out whether the results obtained with norethandrolone could be reproduced in our hospital.

PROCEDURE

Sixteen chronic psychotic male soilers were chosen for this study. One dropped out because of an intercurrent disease which necessitated his transfer to a medical ward; 15 patients remained under observation for 18 weeks. They were incontinent of urine and/or feces. They were ambulatory, reasonably healthy physically, and they had specifically no kidney and bladder trouble and no prostatic hypertrophy. A rectal examination was done and urine retention, if any, was measured. Urine and blood examinations (CBC, blood sugar, NPN, icteric index, and thymol turbidity) were done routinely and repeatedly. The diagnosis, age, length of hospitalization, and duration of soiling of each patient are recorded on Table 1.

All patients were started on a 2-week preliminary observation period. Patients were checked every 2 hours by the ward attendants who recorded all urinary or fecal soilings. Patients were allowed to go to the

toilet on their own volition. None was sent to the toilet unless he had soiled. The result of this 2-week period was taken as a base line of soiling for each individual patient.

After the 2-week preliminary observation period, all patients were started on medication. Half of them received norethandrolone² 10 mg. t.i.d. (Group A), the rest placebo, 3 tablets daily (Group B). The double blind technique was used and the ward personnel and supervisors were told that 2 drugs were being tested to determine whether or not they would affect the soiling habit of patients. In the beginning they suspected that one of these drugs was placebo, but they soon lost their suspicion for obvious reasons. Patients were not informed of the expected action of the drugs.

After 8 weeks the drugs were reversed, patients of Group A who had started with norethandrolone were put on placebo and patients of Group B who had started with placebo were put on norethandrolone. They were again observed for 8 weeks and medication was then discontinued. After 4 weeks

of interruption, the soiling habits were checked again for a post-experimental period of 2 weeks.

Changes were kept to a minimum during the whole study period. Patients who were on any additional drug were continued under the same medication. No new drug, especially no ataractic drug, was added at any time. One variable could not be eliminated, namely, the influence of the season with change from warm weather during which the patients spent their days in the yard to cold fall weather when they had to remain in the dayhall. Analysis of our data did not show any influence of this seasonal change on soiling habits.

RESULTS

On Graph 1, urinary continence in 2-week periods is reported as percentage of the base line established during the preliminary period. Soiling decreased to 27.2% in the norethandrolone Group A and to 35.3% in the placebo Group B during the first 8 weeks of observation. After observation for another 8 weeks under switched medication, soiling in Group A—now under placebo—was 15.6%, in Group B—now under norethandrolone—

² Thanks are expressed to the drug manufacturer, G. D. Searle & Co., who supplied this drug (Nilevar).

GRAPH 1
URINARY SOILINGS

34.6% of the initial value. Twelve of 15 patients reacted in a similar fashion regardless whether they were started on norethandrolone or placebo. The 2 worst soilers (#10 and #12) in the group starting on placebo showed only slight reduction of soiling under placebo as well as under the drug; a third patient (#7) started soiling under drug medication and continued under placebo. If these are eliminated from the list, the urinary soiling in the remaining patients was 9.9% of the initial value in the drug-placebo Group A and 12.9% in the placebo-drug Group B.

Reduction of fecal soiling shown on Graph 2 shows in general the same pattern

GRAPH 2
FECAL SOILINGS

as urinary incontinence. However, as the total number of fecal soilings is small, compared with urinary incontinence, the curve shows some oscillations. At the end of the first 8-week period, fecal soiling in the drug Group A was 57.4% as against 26.5% in the placebo Group B. After 8 further weeks on reversed medication, soiling was reduced to 44.2% and 42.9%.

Of the 6 organic cases in both groups, only 2 showed marked improvement. Three did not improve and 1 became worse. All 9 schizophrenics improved in their soiling habits, 7 of them showing marked improvement (Table 1). Mark Isaacs(3), in a study done in our hospital also found that the very sick schizophrenics benefit most by treatment with placebo.

A final check was made after all medication had been discontinued for 4 weeks. Fourteen patients were again observed for a 2-week period during which no medication was given. (One patient was bedfast during this period and is therefore not included.) Urinary incontinence increased from 15.6% to 22.6% in the drug-placebo Group A and from 34.6% to 53.6% in the placebo-drug Group B (Graph 1). Stool incontinence remained essentially unchanged in Group A and decreased further in Group B (Graph 2). Table 2 shows the remaining percent of soiling during the last 2-week period without medication for the 2 groups taken as a total (N=14). During this period, 4 patients were completely continent of urine, 5 of stools, and 2 of these of both (Table 1).

DISCUSSION

It is evident from Graph 1 that there is no difference in urinary incontinence between those patients who were given norethandrolone and those who were given placebo, both for 8 weeks. After the drugs were switched, urinary soiling continued on a markedly reduced level. Group A then under placebo for the last 8 weeks remained on a lower soiling level than Group B on drug. Fecal incontinence, too, is reduced under treatment with the drug as well as with placebo.

Stewart Wolf(4) defines the placebo effect as "that which is attributable to the administration of an agent but not to its

TABLE 2

pharmacodynamic properties." It is obvious that the beneficial results obtained in the soiling habits of our regressed patients were not due to the pharmacodynamic action of norethandrolone. They must be due to some other factor connected with changes resulting from the execution of this study and possibly including the administration of placebos. The ward personnel suggested that the patients were embarrassed by constant checking and therefore used the toilet more frequently and voluntarily. Patients might have resented the frequent change of trousers after each soiling. Finally, the patient's general mental condition might have improved under the added attention. We have no proof for these surmises. As patients were not told of the expected action of the drug and as most patients were so much regressed that they would not have understood if told about it, improved soiling habits must have been induced by non-verbal communication. The conclusions are obvious:

1. Even the most deteriorated mental patients are likely to react to the administration of placebo and/or procedural changes

on the ward level connected with it.

2. Patients cannot serve as their own controls if conditions are changed in any way between "control period" and "study period," even if this change consists only in more intensive checking and observation.

3. It is suggested that the improvement in soiling habits of chronic psychotic patients observed by Vlavianos and Fink(1) and by Vaisberg, Michael and Saunders(2) was induced by factors other than the pharmacodynamic action of norethandrolone.

CHLORPROTHIXENE¹: A NEW PSYCHOTROPIC ENTITY

J. RAVN, M.D.²

Of all the psychotropic drugs that have become available in recent years, the phenothiazines, and chlorpromazine in particular, have been used most widely. All these drugs have been found toxic in varying degrees to the hepatic, hematopoietic and/or nervous systems and, despite their effectiveness, must therefore be used with caution. To circumvent this problem of toxicity, numerous attempts have been made to synthesize drugs possessing phenothiazine-like pharmacological activity, but which do not belong to this class of drugs. One such compound, chlorprothixene, has been reported as being comparable to chlorpromazine in potency

not been synthesized previously. Its complete chemistry, pharmacology and toxicology have been described elsewhere(1, 2). Briefly, this compound occurs in 2 isomeric forms, of which the trans form is the more active, pharmacologically. The chemical structure of chlorprothixene is much like that of chlorpromazine (Figure 1) except that the nitrogen atom in the phenothiazine ring has been replaced with an unsaturated carbon atom, allowing the side chain to be attached to the ring with a double bond. The replacement of the nitrogen atom appears to be the more important change, since it is this moiety of the phenothiazine

FIGURE 1

and range of therapeutic effectiveness, but far less toxic(1, 2).

CHEMISTRY AND PHARMACOLOGY

Chlorprothixene belongs to a group of compounds, the thioxanthenes, which has

¹ Truxal is the registered trademark of H. Lundbeck and Company, Copenhagen, Denmark, for chlorprothixene hydrochloride.

² Chief, Department K, Middelfart Mental Hospital, Middelfart, Denmark.

molecule that has been suspect of producing toxic reactions.

Chlorprothixene has been used at this hospital in preference to all other psychotropic agents for the past 18 months, during which time over 600 patients have received the drug. Our preliminary appraisals of its effect on psychiatric patients have been presented elsewhere(3, 4). This report concerns the use of chlorprothixene in 258 fe-

male patients, all of whom have received it for 3 months or longer.

CLINICAL EXPERIENCE

Patients—The clinical material is grouped according to diagnoses and is listed in Table 1. Two hundred and five patients had received previous treatment (chemotherapy, somatotherapy and/or psychotherapy) at this or another hospital or by their family physician.

During the evaluation, appropriate laboratory tests were done on varying numbers of patients to determine the effect of prolonged administration of the drug on the hepatic, renal, neurological, and hematopoietic systems. In addition, several groups of patients were followed closely for clinical manifestations of cardiovascular, neuromuscular, and allergic reactions which might be related to the administration of the drug.

Dosage—Chlorprothixene was administered orally or parenterally, depending on the diagnosis and desired response. In patients who were extremely agitated, especially those in manic phases, 20 mg. of the drug was administered intramuscularly 3 to 5 times daily; when necessary, doses as high as 80 mg. were given t.i.d. Infiltrations and tenderness at the site of injection occurred rarely and only after prolonged intramuscular administration; when present, these

effects were far less pronounced than similar reactions observed with chlorpromazine. Once the patient's acute symptoms were controlled, the drug was administered orally. In changing dosage forms, we have found it advisable to reduce the parenteral dose, supplementing it with small oral doses. As doses administered in the latter form are increased, the parenteral dose should be further decreased and, finally, discontinued.

When treatment was initiated orally, the method of administration found most effective in schizophrenic patients consisted of an initial daily dose of 45-90 mg., given in divided doses. Because we found the drug to be relatively free of untoward reactions, we usually increased the dose rapidly every second or third day by total daily increments of 45-60 mg. When a satisfactory response was obtained, usually at daily doses ranging from 400-500 mg. (in a few patients total daily doses were as high as 800 mg.), the patient was maintained on this dose for 2 to 3 weeks, after which time it was slowly reduced to a maintenance level. Depending on the individual's response, daily maintenance doses varied between 45 and 200 mg. In patients with psychoneuroses, and those with endogenous depressive reactions, medication was initiated with 15 mg., t.i.d., and was increased to 30-45 mg., t.i.d.

None of the patients received concomi-

tant psychotropic agents during this evaluation. Somatotherapy was employed only after a patient had failed to obtain an optimal response to chlorprothixene.

Results—Response to treatment was based on improvement shown during personal interviews, changes in behavior and reactions toward other patients and the nursing staff, and increased participation in rehabilitative therapies. The over-all response of the patients is shown in Table 1.

Schizophrenic Reactions—Because they were under observation for longer than any other group, the course of treatment in these 83 patients (average age: 44.5 years) has been completely documented. When evaluated, following an average treatment period of 21 weeks, 67 (80.3%) of the patients improved, 14 of whom were discharged from the hospital. As noted in Table 1, the most outstanding response (70% marked or moderate improvement) was obtained in schizophrenia of the paranoid type. From the results shown in Table 2, it is distinctly apparent that the chronicity of illness is an important factor in the outcome of treatment. Of the 63 patients who had received previous treatment with either chlorpromazine, perphenazine, reserpine, mepazine or acepromazine, 44% responded more favorably to chlorprothixene, 35% responded as well, 6% did not respond as well, and 15% did not respond to any of the drugs (Table 3). Patients who had received previous

treatment with chlorpromazine commented that they did not feel as "heavy" or as drowsy while receiving chlorprothixene. In our experience, patients were more cooperative and communicative in psychotherapy and participated more fully in occupational therapy when they were receiving chlorprothixene than when they were receiving chlorpromazine. Patients who had been disturbed for comparatively short periods of time seemed to respond more rapidly to chlorprothixene than to insulin coma or to a combination of insulin coma and chlorpromazine. These patients became calm and relaxed, and their hallucinations and delusions disappeared; their physical condition was, of course, far better.

Manic-Depressive Reactions—Although the rate of improvement (80%) in this group of patients was comparable to that of the patients with schizophrenia, the degree of improvement (74% marked or moderate improvement) was significantly higher. Sixteen of the patients in the manic phase of their psychoses were extremely agitated and, in the past, 10 of them had required ECT as block therapy. Intramuscular administration of chlorprothixene controlled severe agitation rapidly, and none of the 13 patients with a marked response required ECT during treatment.

All the depressed patients received chlorprothixene orally and began to show signs of improvement within 2 to 3 weeks. Initial-

TOTAL	63

ly, improvement was characterized by fewer sleep disturbances and, several days to a week later, by amelioration of depressive affect, and increased psychomotor activity. Depressive symptomatology recurred in 3 of the patients who had a marked response while receiving chlorprothixene. Thirteen patients, who had not responded fully, were selected for therapy with iproniazid (7 patients) and imipramine (6 patients). Mini-

mal improvement was seen in only 2 patients, both of whom had received imipramine. Twelve of the 13 patients obtained complete remission of symptoms following a course of ECT. The number of patients with cyclical and atypical manic-depressive psychoses is too small, we feel, to warrant discussion.

Miscellaneous Psychotic Reactions—Two of the 11 patients with acute anxiety reactions were in a predelirious condition on admission. The parenteral administration of chlorprothixene averted delirious episodes in both these patients and produced marked improvement in 7 of the remaining 9 patients. In general, the drug shortened the course of treatment in all 11 patients. Chlorprothixene controlled agitation rapidly, and "normalized" the patients' sleeping pattern quickly, making them receptive to psychotherapeutic measures. Ten (71%) of the 14 patients with psychotic depressive reactions showed a marked response to chlorprothixene administered orally and, in general, the course of improvement in these patients paralleled that described for the manic-depressive depressed patients. The depression was not deepened in any patients, nor did it return while the patients were under our supervision.

Psychoneuroses—The results obtained with chlorprothixene in these 65 patients, particularly in those with minimal degrees of anxiety, were comparable to those obtained with many of the currently available tranquilizing agents. On the other hand, however, the results obtained in patients with psychoneurotic depressive reactions differed greatly from those generally expected with a tranquilizing drug and small doses of insulin. As will be noted from Table 1, 31 (86%) of these patients showed a marked or moderate degree of improvement with the oral administration of small (30-90 mg.) daily doses of the drug. Because this degree of response was largely unexpected, it may indicate that chlorprothixene, while it resembles chlorpromazine in chemical structure and basic pharmacological activity, produces its effects through a different mechanism(s) of action which makes it an almost specific form of therapy for psychoneurotic depressive reactions.

TOLERANCE STUDIES

Extensive laboratory tests and clinical observations were made on the first 120 patients who received chlorprothixene, to study the drug's effects on vital physiological function. The results of these studies are given below.

Laboratory Results—On the first 100 patients, total leucocyte counts were made every second day during treatment; eosinophil and platelet counts were determined once a week. Urinalyses, with attention directed specifically to albumin and urobilinogen, were done twice a week. When required, as in patients with a urobilinogen increase of more than 1:10, the Takata-Ara, thymol turbidity and alkaline phosphatase tests were also utilized.

With the exception of one patient in whom a mild leucopenia (total leucocyte count of 2640) was observed, the results of blood studies showed no evidence of this effect. The reaction in this patient was not accompanied by a change in the neutrophils or granulocytes, and cleared spontaneously when the drug was discontinued. A transient eosinophilia was observed in 7 patients, but continual hematological testing during the subsequent 5½ months these patients were receiving the drug, failed to show additional hematological changes. Results of urinalyses and liver function tests remained within normal limits throughout treatment for all patients.

Clinical Observations—The blood pressure of the first 120 patients was measured daily throughout treatment. No abnormal fluctuations were noted. Transitory tachycardia was observed in 28 patients but, particularly since no changes in ECG tracings were found, the clinical significance of this effect was difficult to evaluate. In 5 patients, 20 to 25 mg. of chlorprothixene was administered intravenously while blood pressure measurements were made every other minute. No significant decrease in blood pressure was found during or following the administration of the drug. Sixty-one of these patients were tested daily for orthostatic blood pressure changes. A decrease of 30 mm. Hg. or more was noted in 9 (15%) of the patients; clinical manifestations accompanied this change in 6 patients. To ascertain the drug's

role in producing this effect, a controlled study was initiated. The blood pressure of 60 newly-admitted patients who had not previously received drug therapy and 46 patients who had received psychotropic drugs were tested for orthostatic changes before they were given drugs of any kind. Although clinical manifestations of orthostatic changes were not observed in any of the patients in either of these groups, decreases of 30 mm. Hg. or more were observed in 10 (17%) patients in the former group and 5 (11%) of the latter group. On the basis of these findings, it would appear that chlorprothixene does not contribute significantly to the incidence of orthostatic blood pressure changes found in institutionalized psychiatric patients.

SIDE EFFECTS

None of the more than 600 patients who have received chlorprothixene to date has developed clinical signs of parkinsonism, extrapyramidal disturbances, accommodation paresis, gastrointestinal disturbances or atony of the bladder. Seventeen patients who had developed photo-erythema while receiving chlorpromazine during the summer of 1959 did not demonstrate a similar reaction while on chlorprothixene. Skin reactions were observed in 7 patients. In 3, however, the reaction proved to be an allergic response and not related to the administration of the drug. Chlorprothixene was discontinued in 4 of these 7 patients, but was continued at a reduced level in the remaining 3 with no increase in adverse effects. Dryness of the mouth has been observed in approximately 1/5 of the patients receiving doses greater than 100 mg. a day. One-third of the patients treated to date with large daily parenterally or orally administered doses have complained of "weariness" at the start of treatment; however, this reaction gradually disappears within 1-2 weeks. Transient dizziness has appeared in several patients, but has never been severe enough to require discontinuing the drug. None of the nursing staff developed contact dermatitis from handling the drug.

COMMENTS

An unusual phenomenon not previously observed was noted in 3 of 7 patients who had developed a marked parkinsonism while receiving perphenazine. When given an oral dose of 15 mg. of chlorprothixene after perphenazine had been discontinued for a week, 3 patients became dizzy and nauseous within one hour. When chlorprothixene was administered in the same dose one week later, it was well-tolerated by all 3 patients. Since perphenazine is excreted slowly, we attributed this phenomenon to the potentiating properties of chlorprothixene.

In addition to using chlorprothixene as indicated above, we have also used it with good success in patients in whom narcotics, alcohol, and barbiturates were being withdrawn. One of these patients, a known morphine addict for 30 years was unable to complete withdrawal treatments on 6 previous occasions because of severe abstinence symptoms. When admitted, she had been taking a total weekly dose of 1000 mg. of morphine. Intramuscular injections of chlorprothixene were administered during the withdrawal of the narcotic and the patient scarcely exhibited abstinence symptoms of any kind. In general, the use of chlorprothixene in this type of indication minimizes confusion, restlessness and hallucinations, and allows the patient to regain full control of his facilities, often by the third day of treatment.

SUMMARY

In our experience in treating over 600 patients, 258 of whom are reported on in this communication, chlorprothixene has proved to be an effective broad-range psychotropic agent with a high degree of safety.

MICROPSIA

JEROME M. SCHNECK, M.D.¹

Micropsia has been mentioned as a possible accompaniment of tumors of the temporal or temporosphenoidal lobe. It has also been related at times to episodes of petit mal. But micropsia may occur without apparent neurological defect or dysfunction, and it can be studied as a psychopathological phenomenon. The present case furnished an opportunity to evaluate some aspects of its psychodynamics. It should be of interest because of this, aside from the fact that micropsia is not often mentioned in the literature.

CASE DATA AND PSYCHODYNAMICS

During treatment, and after this 50-year-old patient had been intensively involved in exploring his personality difficulties, he spoke about a period between the ages of 6 and 8 when he experienced many episodes of micropsia. He observed all objects in the room getting smaller and smaller, with an accompanying impression of movement, until they were finally very small and off in the distance. He would feel comparatively large in relation to them. "It was like looking through the wrong end of a telescope." Then, without any impression of movement, the objects would suddenly return to their normal size when "I would shake myself out of it." At such times he felt very frightened. He was aware, during that age period, of feeling intensely lonely, and on re-evaluating this years later he recognized the presence of great anger that had been repressed. Much of the anger was directed at his parents.

The patient's childhood, including the years when he had the micropsia, was recalled as unhappy and unpleasant. His mother was controlling and overprotective. His father was largely unapproachable and lacked understanding. The patient was not permitted the freedom and ease of activity he witnessed in other children. His Jewish background set him further apart from others where he resided and attended school. This was accentuated by foreign elements in his speech, and in the clothing his mother made for him. Among other children he seemed different and strange. He

wanted his own individuality but sought acceptance too. He wanted to express himself but feared reprisal. He wanted to participate but became more the observer. His self-consciousness grew, as did his lack of self-confidence. More and more he felt apart from others while striving to make his own way among them.

The patient developed obsessive-compulsive personality patterns with passive-aggressive conflicts, rigidity, and anxiety in certain interpersonal relations. He achieved ultimately a good measure of success in the entertainment field and was trying, through treatment, to facilitate acquisition of professional goals and greater comfort in social situations by diminishing his rigidity, anxiety, and compulsive behavior. It became evident that power and control meant much to him in various ways on both conscious and unconscious levels.

The micropsia was an apparent reflection of his expansive needs at that time, with an attempt to counteract the hemmed in feeling he was experiencing. "I think it was expressing the wish I weren't confined to a small space. I think it was a reaction to being under great pressure." He believed the micropsia symbolized his wish to be big in relation to all the things about him. It would appear that unconsciously he may have been viewing objects as people, an indication of the trend of his pathology at the time, but a trend that his basic ego strength could hold in check with the avoidance of a psychotic break. The unconscious identification of objects with people and manipulation of the former in the micropsia would be one way in which he could attempt to cope with his intense anger. So in his feeling of weakness he tried to exercise a measure of control in symptom formation of a type which highlighted underlying fantasies of omnipotence. But while he became the large, central figure among all the small things about him, he was frightened in his insecurity. This fright accompanied excursions into fantasy in general, as a child and as an adult. He wanted to possess a great sense of importance but he felt uncomfortable nevertheless. While he wished to be liked, he craved respect.

The micropsia with the associated impression of movement of objects away from the patient was consistent with his sense of separation from people and things about him during that age period and to varying degrees into

¹Clinical Associate Professor of Psychiatry, State University of New York College of Medicine, New York City.

his adult life. The phenomenon was a reflection of his sense of loneliness.

The patient's micropsia occurred only in his own room when he was alone. He was considered frail by his parents who in their over-protectiveness would send him there to rest. Deprived of other activities, he felt annoyed. Through the years he was troubled by headaches, and he recalled that they were especially severe during the period when the micropsia was also experienced. It would seem that this symptom too was related to repressed hostility. The headaches subsided only during recent years.

It is of interest that the patient stated, without reference to the micropsia, that people seemed "large" to him, adding this was "speaking metaphorically," and that he seemed small in proportion. He had in mind their comparative abilities, ease of verbal expression, flow of ideas, quickness in seeing a point of view, and similar attributes. In these he regarded himself as inferior.

PSYCHODYNAMICS AND OTHER REPORTS

Sexualization of vision is widely known and has attracted much attention. Fenichel (1) summarized a variety of visual problems in this connection, stressing the eye as representative also of a pregenital erogenous zone. It can express oral-sadistic and oral-incorporative longings. In connection with micropsia, he makes a point of its serving as a defense against oral-sadistic strivings. One of Inman's cases is used as an example. Inman discussed micropsia in 2 boys. For them, objects symbolized the mother. The symptom appeared when intense oral needs were frustrated (2). I believe the inference in Inman's cases pertaining to the breast getting smaller and smaller would appear to fit in with the history of my patient. There is the ambivalence toward his mother, his strong feelings of deprivation, and his great anger. In his adult life, obvious evidences of oral conflicts were present in excessive smoking with unsuccessful efforts to control it, frequent episodes of overeating to the point of discomfort, and excessive concern with clarity of verbal expression, ability to make impressions on others in conversation, and to influence them through able verbal tactics.

Lewy reported that in his case the micropsia expressed endopsychic perception of ego disintegration that was imminent or

beginning (3). Object loss due to withdrawal of libido was also imminent or partially established. The endopsychic perception was projected into the outer world. Lewy's patient was 17 years old, and when hospitalized he appeared to have "a severe obsessional neurosis with schizophrenic coloring." Later he had periods in which he was confused and hallucinatory, with ideas of reference. Lewy mentions that his patient's reports of micropsia were vaguer than other references in the literature in that the appearance of objects moving away from him does not stand out clearly, and the idea of seeming to see things through the wrong end of a telescope was not as pronounced as with others. He felt justified, however, in classifying the case with others labelled micropsia. In connection with these reservations I note that his patient felt himself to be small too, along with the objects he saw. Lewy observed that the micropsia occurred in his patient when ego defenses were crumbling. I suspect that this trend paralleled a phase my own patient was experiencing, although for him it was not to reach the proportions of a psychotic episode as in the case presented by Lewy.

The oral fixations and aggressive components in my case and others were noted also by Bartemeier (4). His 28-year-old female patient began to have micropsia at the age of ten. The general theme pertains to aggression and the defense against it finding representation in the micropsia. More specifically, aggression may involve the function of the eye as a symbolically murderous weapon, a point which Fenichel chose to focus on when he commented on micropsia. Bartemeier's patient had fewer episodes as she grew older. Lewy took issue with Bartemeier on the differentiation between micropsia as a psychogenic reaction and that which accompanies neurological defects, the sense of movement into the distance being present in the former, and sudden appearance of objects as small and far away in the case of the latter. He doubted the ability to distinguish between them. I hesitate to offer an opinion based on my own clinical experience. The only other case of micropsia I recall definitely having encountered was that of a young man in his twenties, seen in consultation 15 years ago during military

service. His emotional disturbance appeared to involve schizophrenic elements. He described episodes of micropsia clearly. Unfortunately I had no opportunity to study the patient intensively or to investigate specifically the psychodynamics of his micropsia.

SUMMARY

Micropsia may accompany neurological defect or dysfunction as in tumors of the temporal lobe and petit mal. It may be encountered as a psychopathological phenomenon without structural defect. It is described relatively infrequently in medical literature. The symptom involves seeing objects or people as very small, off in the distance, as if one were looking "through the wrong end of a telescope." An impression of objects moving away, into the distance, is often described. A patient in psychiatric treatment told of a series of such episodes during his childhood. His micropsia apparently reflected his expansive needs counteracting a closed-in feeling, his reaction to heavy psychological pressures, an attempt to cope with intense repressed anger, a way of symbolically manipulating people identified as objects, and a method

of exercising control to cope with feelings of weakness and insecurity. The micropsia was a mirror of his feeling of separation from people and things about him during those childhood years, and it serves as an indication of his loneliness. It was a sign of diminishing ego strength, but was not followed by a psychotic break. Defenses were evidently reinforced later, judging by the patient's history and the personality patterns that evolved. The oral and aggressive components in this case were witnessed by others in studies of their patients. Pertinent references are mentioned here, and the observations integrated with my own findings. Similarities and differences in the cases are noted. Finally, mention is made briefly of another patient of mine with micropsia although there was no opportunity to evaluate the psychodynamics of his problem.

SEXUAL DISORDERS AND BEHAVIOR THERAPY

S. RACHMAN, Ph.D.¹

"Behavior Therapy" is a term used to describe a number of new psychotherapeutic methods which have been developing rapidly in recent years. Although the actual procedures vary from aversion conditioning to desensitization they all have a common theoretical basis(3, 4, 7, 9, 14).

A brief account of this rationale may be stated as follows: the position adopted by this theory is that neurotic behavior is acquired. The process of acquisition implied in the theory is derived from modern learning theory. If neurotic behavior is regarded as being acquired, then it must follow that such behavior will be subject to the established laws of learning. Current knowledge about the learning process concerns not only the acquisition of new habit patterns but also their elimination. The elimination of learned responses occurs either by the extinction process or by inhibition.

Wolpe(14) has defined neurotic behavior as "any persistent habit of unadaptive behavior acquired by learning in a physiologically normal organism." Anxiety is "usually the central constituent of this behavior, being invariably present in the causal situations." Similarly, Eysenck(3) postulates that "neurotic symptoms are *learned patterns of behavior* which for some reason or another are *unadaptive*." It should be noted, however, that neurotic symptoms may under certain circumstances also result "not only from the learning of an unadaptive response, but from the failure to learn an adaptive response"(3). A common example of this type is enuresis nocturna. The relearning and/or un-learning techniques which have been used therapeutically so far include: (Aversion conditioning (chemical or electrical), Desensitization based on relaxation, Training in assertive behavior, Use of sexual responses, Use of feeding responses, Extinction based on negative practice, Anxiety-relief responses. With the exception of the last 3 techniques, all of these methods have been used in the treatment of

various sexual disorders.

Although behavior therapy has been used in only a comparatively small number of cases of sexual disorder so far, the results have been promising. The purpose of the present paper is to give an account of the findings and to suggest further lines of development.

The disorders of sexual behavior which have been treated by behavior therapy include impotence, frigidity, voyeurism, fetishism, exhibitionism, homosexuality and transvestism.

Impotence: Wolpe(14) reports the successful treatment of 7 cases of impotence using the methods of behavior therapy, and Lazarus and Rachman(16) give an account of one successful case treated by these methods. The mean number of sessions taken to improve Wolpe's 5 "apparently cured" cases was 14.4, and 75 sessions to produce the changes in the 2 "much improved" patients. The 2 latter patients were also diagnosed as suffering from interpersonal anxiety. None of the apparently cured patients had this symptom but 2 of them had phobias associated with their impotence. Another difference between the apparently cured and much improved patients is to be found in their neurotic tendency scores (obtained by the Willoughby Scale). The mean score for the cured patients was much lower (26.5) than that of the improved patients (51.5). These differences suggest the possibility that impotence associated with high neuroticism scores and/or interpersonal anxiety may be more resistant to behavior therapy.

The 3 methods of treatment used in these impotence cases were: desensitization, use of sexual responses, use of assertive responses. The desensitization method has been described in detail by Wolpe(14) and Rachman(7). Briefly, it consists of inhibiting the anxiety responses provoked by phobic or noxious stimuli. The lasting inhibition of these responses is gradually developed by the controlled and systematic evocation of anxiety followed by relaxation. The thera-

¹ Institute of Psychiatry, University of London, London, England.

pist begins by presenting only mildly disturbing visual images. Each presentation of a noxious image is immediately followed by deep relaxation. When the emotional effect of the milder images has been considerably reduced or eliminated, the therapist then presents slightly more disturbing images until even the most anxiety-provoking situation can be pictured without disturbing the patient. This procedure of gradually working along the patient's hierarchy of disturbing objects or situations may take from one to a hundred or more sessions depending upon the severity and complexity of the syndrome. Before starting the process of desensitization, the therapist trains the patient in the methods of deep relaxation (with or without hypnosis).

The second technique, the use of sexual responses, is based on theoretical grounds similar to those of desensitization. The use of sexual responses is particularly valuable where the sexual behavior is only partially inhibited. "The patient is told that he must on no account perform sexually unless he has an unmistakable, positive desire to do so, for otherwise he may consolidate or even extend his sexual inhibitions" (14). The patient may be advised, for example, to engage several times in sexual activities (with the understanding of his partner) without attempting intercourse. With each repetition of relaxed sexual play in which no criterion is set, the patient's anxiety decreases. When a significant decrease in anxiety has been achieved the patient is advised to attempt intercourse only if and when he feels *strongly* impelled to do so. Wolpe states that patients instructed in this way experience "increasingly strong erections, and usually after a few sessions coitus is accomplished and then gradually improves."

The third technique, the use of assertive responses, Wolpe derived partly from Salter (12) and is useful in overcoming social inhibitions and anxiety. The patient is trained to use assertive, expressive behavior particularly in those social situations (or more usually, with specific types of people) which provoke anxiety. The aim of this technique is to develop an inhibition of social anxiety by the use of assertive behavior.

In all but one of the 7 cases treated by

Wolpe, the use of sexual responses was combined with one or both of the two associated procedures. In the case reported by Lazarus and Rachman, the methods of relaxation and systematic desensitization were used in the successful treatment of a 32-year-old male patient.

The indications are that the methods of behavior therapy are of value in treating impotence. There is also reason to believe that the methods used in treating impotence could be equally applied to cases of frigidity. To date however there is only one recorded case of this type. Wolpe (14) successfully treated a woman complaining of frigidity and interpersonal anxiety by a combination of desensitization and the use of sexual responses.

Exhibitionism: Bond and Hutchison (1) obtained marked improvement in a patient with a severe and long-standing case of exhibitionism by using the reciprocal inhibition technique. The patient was a 25-year-old married man of average intelligence. His first exposure occurred at age 13 following sex play with a younger girl. His exhibitionism continued throughout adolescence and had reached "bizarre proportions" by the time he reached adulthood. The attacks of exhibitionism were preceded by tension, dread and sexual excitement. Attacks were often provoked by the perception of attractive young women.

The antecedent tension was constant and the patient often exposed several times a day. He had been convicted of indecent exposure on 11 occasions and had as a result spent a considerable amount of time in detention.

The severity of his condition is best illustrated by the author's account, "A frequent practice was to hide completely nude in a small wooded area in the centre of the town where he then lived, and spring out and expose himself to the first woman who passed." Various types of therapy had failed to relieve his condition.

It was decided to attempt Wolpe's desensitization procedure and the patient was accordingly trained to relax. A hierarchy of exposure-provoking stimuli was constructed and the patient gradually desensitized over a period of 30 sessions. By the eighth interview the patient evidenced distinct improve-

ments. He was less tense, less prone to expose himself and able to venture out unaccompanied. As the desensitizing therapy continued, further evidences of progress appeared. His exhibitionist urges declined in frequency and strength, his sexual fantasies diminished and he reported an improvement in his sexual relations with his wife.

Therapy had to be discontinued after 29 sessions but the patient reported in succeeding months that he continued much improved. He then exposed himself in a feeble and uncharacteristic manner in a store. The patient was returned for treatment on a weekly basis and 2 months later no relapse had occurred.

Bond and Hutchison's view is that

exposure either follows some environmental stress . . . or is provoked by an encounter with a female of specified age and physical appearance . . . The exposure can be thought of as an instrumental act designed to reduce an anxiety response cued off by certain classes of stimuli, and desensitization therapy would constitute an appropriate form of treatment.

This account provided by Bond and Hutchison conforms to a case treated by Wolpe (14).² He obtained marked improvement in a 25-year-old patient with a history of exhibitionism dating back to childhood. This patient also suffered from social anxiety and had particular difficulty with authority relationships. The impulse to exhibit frequently arose after frustration or anxiety had been induced by his submission to authority. Treatment consisted of instigating assertive behavior and desensitization to social situations which provoked anxiety. Wolpe (15) states treatment results :

a tremendous general increase in well-being and heightened ability to deal adequately with social situations. Nevertheless a small degree of autonomous tendency to exhibit, apparently purely sexually based continued and only ceased when the patient married in 1956.

Voyeurism : There is 1 case report of a voyeur who was markedly improved by behavior therapy (14). In this case, as in some

² I am grateful to Dr. Wolpe for supplying additional information on this and other cases reported in his book (14).

of the homosexuals discussed below, the sexual disorder disappeared as the patient's other symptoms improved. A 40-year-old male complained of writer's cramp and voyeurism. Clinical examination revealed the presence of deep and long-standing interpersonal anxiety however. Assertive training and desensitization were initiated and a considerable improvement in the patient's social behavior was obtained at the end of 5 months. The voyeuristic impulses "had completely disappeared even though beyond some discussion of its relation to frustration no specific treatment was directed against it" (15).

Transvestism : Davies and Morgenstern (2) report an unsuccessful attempt to treat a transvestite patient by apomorphine aversion conditioning. It is impossible however to ascertain any possible effects of this therapy on the patient because of the marked organic syndrome involved. The patient had temporal lobe epilepsy and cerebral cysticercosis. The authors concluded that the transvestite behavior could be curbed in the hospital but not at home.

Fetishism : After examining the literature, Raymond (10) was able to find only 3 cases of fetishism in which treatment had produced successful results. Although this disorder has been extensively described, it remains extremely resistant to therapeutic modification. For this reason Raymond's successful treatment of a fetishistic patient is of considerable interest and value.

A 33-year-old married man was given treatment on probation after having been convicted of causing wilful damage to a perambulator. Since the age of 10 he had been fetishistically attracted by prams and handbags. These objects aroused him sexually and he obtained a release of tension by attacking them. The attacks on prams had resulted in several convictions and he had spent several periods in mental hospitals. He had not benefited from previous therapy including psychoanalysis.

Raymond constructed a conditioned aversion programme similar to that used in the treatment of alcoholism. The patient was shown a collection of handbags, prams and colored illustrations, "after he had received an injection of apomorphine and just before nausea was produced." Treatment

was given 2-hourly day and night, no food was allowed and he was kept awake with amphetamine. Treatment was suspended after 1 week and the patient went home temporarily. He returned 8 days later and reported some progress. Treatment was then continued for a further 9 days. By this time he was showing strong aversion to the fetishes. The patient was then seen at an outpatient clinic for a period of 6 months. A booster course of treatment was then given in the hospital.

Nineteen months later the patient "still appeared to be doing well." He no longer had fantasies concerning handbags and prams, his sexual relations with his wife had greatly improved, his probation officer reported very noticeable progress and he had no further trouble with the law.

Raymond favours Binet's theory that the "predisposition to fetishism . . . may be in an unusual capacity to develop conditioned responses and that this capacity may be used as an asset in treatment."

In a case seen recently by the present writer faradic aversion therapy was attempted. The patient was a 32-year-old bachelor who was sexually aroused by women's buttocks and bloomers. He had never had intercourse but masturbated with fantasies concerning these fetishes. The patient was given 5 aversion conditioning sessions. Three stimulants were used: the patient's photographs of women wearing bloomers, visual images of women with attractive buttocks, visual images of bloomers. The electric shocks were administered with an induction coil and finger electrodes. The patient was given 10-15 trials with each stimulus at each session. The strength of the shock was gradually increased after every 4 trials. During the first session the patient complained that the visual image of buttocks was constantly with him. At the fifth session he could only obtain the images with great difficulty. The time elapsing between the instruction to obtain the image and its appearance was found to increase significantly from session to session. After the final session the patient reported feeling better and said he no longer felt attracted by buttocks, had ceased having his former fantasies and had disposed of his numerous pornographic photographs. Unfortunately it is impossible to draw any firm conclusions from this pilot study since the therapeutic program was not completed and because the case was considerably complicated by several other abnormalities, includ-

ing transvestite impulses, and was receiving other forms of treatment at the same time as the conditioned aversion sessions.

Homosexuality: Freund(5) remarks on the pessimism often expressed by therapists regarding the treatment of homosexuals and argues that insofar as psychotherapy has any beneficial effect, this is attributable to a particular causal element. This causal element, he says, is "the encouragement of behavior patterns which emphasize restraint or complete abstinence from homosexual behavior, and which involve heterosexual behavior." Freund accordingly devised a conditioning programme designed to inhibit homosexual and stimulate heterosexual behavior. He adapted and developed the aversion procedures commonly used in the treatment of alcoholism.

Freund's treatment consisted of the administration "of an emetic mixture by subcutaneous injection." While the noxious effects of the injection were being experienced the patient was shown slides of dressed and undressed males. In the second phase of the treatment, the patient was shown films of nude and semi-nude females approximately 7 hours after the administration of testosterone.

Freund reports the results of this type of therapy on 47 patients. Follow-up studies 3 and 5 years after treatment indicated that 51% of the patients showed no improvement; 14.9% temporary improvement; 25.5% permanently improved; the remaining 8.5% were not adequately documented and hence excluded from the final analysis.

Freund concludes that his therapeutic results do not differ in quality or degree from those claimed by other methods. Such rule-of-thumb comparisons with other reports are, however, of little value because of the numerous variations in patient selection, evaluation of outcome and other important but uncontrolled variables. It is a great pity that Freund did not include in his otherwise valuable study a matched control group. Another important aspect of this treatment which would repay investigation is the effect, if any, of booster treatments such as that used by Raymond(10) in his treatment of a fetishist. For example, would boosters reverse those cases which relapsed

or, better still, prevent them from relapsing at all? An interesting innovation is the systematic inclusion of positive, adient stimulation which complements the aversion therapy.

An early attempt to use aversion conditioning is found in a brief report by Max (6). He claimed the successful treatment of a homosexual with the use of faradic aversion conditioning. Unfortunately it is impossible to assess the value of this report because of its brevity. Stevenson and Wolpe (13) recently reported the successful treatment of 2 homosexuals using non-specific behavior therapy. They were able to produce marked improvements in these cases with the use of assertive training, desensitization and environmental manipulations. The importance of this study is that it illustrates how a sexual disorder may be treated in a non-specific manner by improving the patient's mental health generally.

Despite the considerable amount of literature on the subject, the nature and causation of homosexuality are still unclear. If we are to make progress in the treatment of this disorder more investigations like that of Freund will have to be conducted. These further studies should include control groups and also explore the possibility of substituting faradic for chemical aversion procedures. In addition, further attempts should be made to treat homosexuals in the non-specific way used by Stevenson and Wolpe(13) in those cases where such a procedure appears appropriate.

DISCUSSION

On the evidence available it is fair to conclude that behavior therapy may prove valuable in the treatment of sexual disorders. Perhaps the best attitude at this stage is one of cautious optimism.

The most convincing advance so far has been in the treatment of impotence and, possibly, frigidity. On voyeurism, fetishism and exhibitionism more clinical trials are needed. In cases of homosexuality it seems that there is a need for more carefully designed methods and information concerning the nature of this disorder.

All the methods employed to date, ranging from aversion conditioning to assertive training, have been justified to some extent

at least. It is probable that most cases require a combination of the available methods. It is to be hoped that these techniques will be refined with further experience and also that new procedures will be forthcoming.

Some suggestions for developing the behavior therapy methods can already be offered on the basis of present knowledge. One possibility is the greater use of faradic as opposed to chemical aversion conditioning. Some of the advantages promised by faradic aversion conditioning are that it permits 1. More precise control of the situation by the therapist; 2. Greater flexibility in manipulating both the conditioned stimulus and the unconditioned stimulus; 3. More accurate and systematic measurement of the patient's specific responses and, hence, his general progress. In addition, the faradic method makes less demands on medical and nursing staffs and can often be conducted on an outpatient basis.

A second possibility is the use of Wolpe's (14) anxiety-relief technique in the treatment of voyeurism, exhibitionism and fetishism. There is a hint present in the few cases reviewed here and elsewhere(11) that in many of these patients the abnormal sexual act is preceded or precipitated by an accumulation of tension. The anxiety-relief technique is designed to produce greater control of anxiety or tension and may, therefore, prove useful in such cases. Briefly, the technique is as follows. The patient is given a strong electric shock and told to say the word "calm" when the pain and tension become unbearable. At this, the therapist switches off the current and the patient experiences considerable relief. This procedure is repeated 10-20 times per session with one minute rest periods between trials. In this way the patient is given a degree of voluntary control over his feelings of tension and anxiety. Naturally, this method must be used with caution.

A third suggestion is provided by Freund's(5) treatment of homosexuality in which he emphasizes the necessity for stimulating and encouraging positive sexual behavior in addition to eliminating abnormal sexual activities. It may often prove unwise to concentrate on the negative aspects of the patient's behavior and hope or assume

that adaptive sexual activity will automatically follow. Wolpe's use of sexual responses is an important method to be borne in mind for this purpose.

SUMMARY

An account is given of the available results of behavior therapy in the treatment of sexual disorders. To date attempts have been made to treat impotence, frigidity, voyeurism, exhibitionism, transvestism, fetishism and homosexuality. The results suggest that the methods of behavior therapy can be applied with success in treating sexual disorders. Some additional suggestions are made.

FACTORS IN SELECTION OF PSYCHIATRIC TREATMENT FOR INSTITUTIONALIZED AGED PERSONS

ROBERT L. KAHN, Ph.D., ALVIN I. GOLDFARB, M.D.,
MAX POLLACK, Ph.D., AND ARTHUR PECK, M.D.^{1, 2}

Recent investigations have shown that not only the type of illness but also sociopsychological factors influence the type of psychiatric treatment a patient receives. As shown by Hollingshead and Redlich(2), persons from the upper social classes, as defined by education, occupation and place of residence, are more likely to be selected for psychotherapy, while somatic treatment or custodial care is more common among the lower social groups. Rosenthal and Frank (6) reported an almost straight line relationship between educational level and frequency of referral for psychotherapy in an outpatient clinic. In another clinic, Myers and Schaffer(5) found that the higher a person's social class the more likely he was to be accepted for psychotherapy and treated by highly trained personnel intensively over a long period of time. In a study of a private, nonprofit mental hospital, Kahn, Pollack and Fink(3) found that better educated, native-born and younger patients were most likely to receive psychotherapy as their sole form of treatment, while EST was more frequently prescribed for the older, foreign-born and more poorly educated patients.

This paper reports on a systematic investigation of the relation of specific characteristics in residents of a home for the aged to the selection of psychotherapy, other forms of psychiatric treatment or no psychiatric treatment.

METHOD

The population studied was a random sample of 160 persons, 65 years of age and over, residing in the Home for Aged and Infirm Hebrews of New York.

¹ From the Office of the Consultant on Services for the Aged, New York State Department of Mental Hygiene, Queens Village, N. Y., and the Home for Aged and Infirm Hebrews of New York.

² We are grateful for the cooperation of Frederic D. Zeman, M.D., Director of the Medical Services of the Home for Aged and Infirm Hebrews of New York.

A staff psychiatrist examined each patient and entered his observations in a standard way on a precoded form. The psychiatrist noted the presence or absence of chronic brain syndrome or other psychiatric disorder, the degree of the disorder, an opinion as to the need for psychiatric treatment, and the type of treatment indicated.

In addition each patient was given 2 brief psychological tests of mental status. These were a 10-item questionnaire testing orientation, memory and general information, and the "Face-Hand Test," measuring ability to perceive two tactile stimuli simultaneously applied to the face and hand(4).

The relationship of the recommendations for psychotherapy, "other" psychiatric treatment, or no treatment to specific characteristics and performance of the patient was correlated.

RESULTS

Recommendation for Psychiatric Treatment: In the psychiatrist's opinion, 84% of the 160 persons needed psychiatric treatment. Psychotherapy was the treatment recommended for 26% of the group; a recommendation for "other treatment" such as milieu therapy or drugs was made for 58% of the group; 16% were not considered in need of any psychiatric care.

Education: The relation between the type of psychiatric treatment recommended and educational background of the patient is shown in Table 1. Patients recommended for

TREATMENT RECOMMENDED		MEAN EDUCATION	DIFFER- ENCE	t
Psychotherapy	(42)	8.7		
Other Treatment	(71)	7.2	1.5	2.32*
No Treatment	(21)	8.1		
Total	(134)	7.8		

* Significant at .05 level.

psychotherapy had a mean educational level of 8.7 years, whereas those recommended for other forms of treatment had a mean of only 7.2 years. The difference between these groups was significant at the 5% level. Patients for whom no psychiatric treatment was recommended had an educational level of 8.1 years.

Age: As shown in Table 2, the patients

TABLE 2
Psychiatric Treatment Recommendation and Age

TREATMENT RECOMMENDED	MEAN AGE	DIFFER- ENCE	t
Psychotherapy (42)	79.4	2.8	N.S.
Other Treatment (88)	82.2		
No Treatment (23)	78.7		
Total (153)	80.9		

recommended for psychotherapy were, on the average, almost 3 years younger than patients recommended for "other kinds" of psychiatric treatment, although the difference is not statistically significant. The group for whom no psychiatric treatment was recommended was slightly younger than the psychotherapy group.

Sex: The sample was predominantly female, reflecting accurately the population of the Home. Males (27% of the sample) constituted 21% of those for whom psychotherapy was recommended, 28% of those for "other treatment" and 32% of the group for whom no treatment was recommended. These differences fall short of statistical significance.

TABLE 3
Psychiatric Treatment Recommendation and Sex

TREATMENT RECOMMENDED	PERCENT	
	MALE	FEMALE
Psychotherapy (42)	21%	79%
Other Treatment (93)	28%	72%
No Treatment (25)	32%	68%
Total (160)	27%	73%

Chronic Brain Syndrome: The relation of treatment recommendation to the evaluation of chronic brain syndrome is shown in Table 4. There was very little difference be-

TABLE 4
Psychiatric Treatment Recommendation and Evaluation of
Severity of Chronic Brain Syndrome

TREATMENT RECOMMENDED	CHRONIC BRAIN SYNDROME PERCENT	
	NONE OR MILD	MODERATE OR SEVERE
Psychotherapy (42)	64%	36%
Other Treatment (93)	57%	43%
No Treatment (25)	80%	20%
Total (160)	63%	37%

tween the group recommended for psychotherapy or "other treatment" with respect to the presence or severity of chronic brain syndrome. Sixty-four percent of the psychotherapy referrals were rated as having no or mild CBS as compared to 57% of the "other treatment" group. In contrast, 80% of the no-treatment group were so rated.

Mental Status Questionnaire: A marked difference between the psychotherapy and other treatment groups was shown for number of errors on the Mental Status Questionnaire (MSQ). Eighty-six percent of the "psychotherapy" group made less than 3 errors, but only 63% of the "other treatment" group did as well, a difference significant at the 1% level of confidence. The "no-treatment" group fell in between with 76% making so few errors.

TABLE 5
Psychiatric Treatment Recommendation and MSQ Error
Score

TREATMENT RECOMMENDED	MSQ ERRORS PERCENT	
	0-2	3-10
Psychotherapy (42)	86%	14%
Other Treatment (93)	63%	37%
No Treatment (25)	76%	24%
Total (160)	72%	28%

Face-Hand Test: Of the persons recommended for psychotherapy 77% were negative on the Face-Hand Test, compared to only 44% of those recommended for other treatments (Table 6), a difference significant at the 2% level. The "no-treatment" group fell in between, with 68% negative.

DISCUSSION

In general, psychiatric values have tended to restrict the use of psychotherapy to young

adults. In recent years more interest has been shown in treating older persons by such methods. The selection of patients for psychotherapy, however, still appears to be influenced by a number of social factors which tend to eliminate older persons. The high percentage of persons recommended for psychotherapy in The Home for Aged and Infirm Hebrews is notable especially because almost all the residents were foreign born and many had difficulty in speaking English. These are factors which militate against referral for psychotherapy in our society. The Home, however, has pioneered in the use of psychiatric treatment, including psychotherapy, with the aged(1). The staff psychiatrist doing the evaluations for this study undoubtedly more readily recommended persons for psychotherapy than is customary. Nevertheless, our study has shown that even in this institution referral for psychotherapy is influenced by social and cultural characteristics of the patient. Referral for psychotherapy is more likely to be made with persons who are better educated, who are more alert and who are operating at higher levels of intellectual functioning. There is also a slight tendency for psychotherapy to be recommended more often for females, younger persons, and those without chronic brain syndrome, but these differences fail to be statistically significant. In general then, the selective factors evidently affecting their recommendations for psychotherapy are still comparable to those noted in studies of other populations.

The most common interpretation advanced to account for the relationship of sociopsychological factors to selection of psychiatric treatment is that psychiatrists tend to select for psychotherapy persons

who are most like themselves in terms of their social characteristics.

Kahn, *et al.*(3), have emphasized that the critical factor in selecting patients for psychotherapy may be the possible communicative interaction between therapist and patient. From this point of view it is understandable that those persons who are better educated, functioning at a superior intellectual level as measured by the Mental Status Questionnaire, and more alert as measured by the Face-Hand Test, would be more appealing to the psychiatrists as possibilities for psychotherapy.

These findings are of importance because they appear to illustrate that psychiatrists believe that a psychotherapeutic relationship requires discriminatory capacity, conversational ability, good memory, and interest in establishing and maintaining a patient-doctor relationship. This psychiatric attitude is contrary to what is often actually discovered in medical and psychiatric practice. Experience with aged ill patients has revealed that brain-damaged, poorly educated persons with disturbance of orientation, memory and desire can make use of supportive personal relationships. They can benefit from a controlled patient-doctor relationship in which the development of insight is not an aim. It is possible that the very characteristics which provoke their rejection as candidates for psychotherapy may be indications rather than contraindications for such treatment. As has been pointed out(1) the helplessness of the brain damaged person who has limited intellectual resources on account of early social and educational deprivation may be more amenable to personal treatment techniques which involve implicit suggestion and are contingent upon his rapid and complete delegation of special powers to the physician.

CONCLUSION

The selection of aged patients for psychotherapy appears to follow the same sociopsychological trends as in younger persons. This manner of selection may tend to weed out the most helpless, anxious and most psychotherapeutically malleable candidates for psychiatric care.

CLINICAL NOTES

(The Clinical Notes report the findings of the authors and do not necessarily represent the opinions of the Journal.)

THE TREATMENT OF ANXIETY IN PRISON INMATES

HARVEY BLUESTONE, M.D.¹

The value of the tranquilizers in the mental hospitals is well established, but less well-known is their usefulness in the penal institutions. Emotional disorders are common to both and it would not be an exaggeration to say that more problems in management are apt to be found in the latter.

Reaction to stress takes many forms in prison inmates as a result of confinement, boredom, close and continuous contact, lack of privacy, aberrant sexual behaviour as well as the response to sexual overtures. The anxiety induced by these pressures may thus range from mild neurosis to severe emotional disorders, and the management of these in a prison population poses difficulties not encountered elsewhere and which tax the patience and judgment of the attending physician. Not only must he consider the desired clinical effect, but he must always be mindful of other considerations peculiar to such an institution. Thus, transfer of medication, frequently by sale, from one inmate to another, is commonplace and requires careful screening of the patients as well as rigid supervision of drug therapy, both in amount and kind.

It may seem surprising, but it is here that a drug may assume a "status" symbol, depending on its effect on cortical function. Barbiturates fall into this category because of the changes in sensorium they induce, or, as they are called by addicts or potential addicts, "kicks." As a result, the use of barbiturates has declined progressively, especially with the advent of the phenothiazines.

Extensive experience with these agents has demonstrated their value in the treatment of tension and anxiety as well as in various psychosomatic disorders, such as

headache, gastrointestinal disorders, and palpitations. As in other institutions, each new compound has been tested in an effort to determine whether it provided advantages over therapies previously in use, with different criteria obviously in mind. The introduction of chlorpromazine was probably the most significant change, superseding as it did the barbiturates which were then prescribed where a "sedative" was indicated. However, and somewhat paradoxically, excessive motor inhibition tended to reduce the usefulness of this compound. In addition, extrapyramidal stimulation introduced an element disturbing to these patients, and this in general, has been the greatest liability to this and succeeding phenothiazines.

More recent experience with thioridazine (Mellaril) as evaluated in 85 cases has been uniformly satisfactory, both subjectively and objectively. Its efficacy in relieving tension and agitation has been reflected in improved sleep, and insomnia is not as frequent a complaint as heretofore. As a matter of fact, this has resulted in a high degree of patient acceptance, so much so that one must consider the psychological factors that are known to occur in placebo response. On the other hand, valid effects which constitute definite advantages include the lack of any stimulant effect, thus facilitating its use for legitimate medical reasons. In addition, the absence of extrapyramidal symptoms has been confirmed in these patients, as has the low incidence of side effects. Jaundice, skin rash or other allergic manifestations have not been observed, and frequent blood checks have failed to reveal any signs of blood change. Drowsiness has been reported by some and has been controlled through a reduction in dose. Generally, dosage has

¹ Chief, Psychiatric Service, Sing Sing Prison, Ossining, N. Y.

ranged from 75-200 mg. daily, with duration of therapy varying considerably according to period of commitment.

SUMMARY

The phenothiazines exert a therapeutic

activity having great value in penal institutions. Experience has demonstrated that the toleration to thioridazine and its clinical effect make it a drug that is very helpful in the treatment of anxiety in prison inmates.

CONTROLLING THE CHRONICALLY DISTURBED PATIENT WITH MASSIVE PHENOTHIAZINE THERAPY

ROBIE T. CHILDERS, JR., M.D.¹

This report deals with the manner in which the problem of the chronically disturbed patient has been handled on a 50-bed ward that is used for the management and treatment of disturbed, hyperactive, resistive, and combative female patients from other sections of a 1800-bed state hospital.

Chronic schizophrenic patients with infrequent and/or acutely disturbed episodes as well as cyclic manic excitements usually respond to moderately large dosages of tranquilizers (such as 1000 mg. Thorazine) or a short series of ECT. The main problem over the years has been how to deal with the chronically disturbed and combative patient who causes unrest amongst the other patients on the ward. There were 8 patients who fit into this category; six carried a schizophrenic diagnosis, one was a mental defective with psychosis and the other was a convulsive disorder with psychosis. They ranged in age from 26 to 63 (average age 38). Length of hospitalization varied from 1½ years to 13 years (average 7½ years).

All patients were combative and had required seclusion or restraint. Other symptoms included hyperactivity, irritability, destructiveness, hostility, and hallucinations. All except one had had one or more definitive attempts at control with either tranquilizers, ECT, or the combination, with only temporary or insignificant improvement.

On the regimen as indicated in Table 1 all 8 patients showed marked improvement. Hostility and combativeness disappeared or was markedly diminished both

in frequency and intensity; 5 of the 8 patients now participate in ward work and recreation. One patient has improved sufficiently to be placed on a convalescent leave.

The "massive dosages" given these 8 patients have not resulted in drowsiness, dizziness, or disinterest. One displayed a tremor on Prolixin and another developed an oculogyric crisis on chlorpromazine but both were immediately controlled on Cogentin. This low incidence of side effects dramatically contrasts with the usual 40% to 50% incidence reported by others and seen by myself in the treatment of patients with much smaller dosages. For purposes of comparison we have equated the 3 drugs used as follows: 5 mg. Prolixin equals 10 mg. Stelazine equals 250 mg. Thorazine.² The 8 patients described in Table 1 received an average of 1700 mg. Thorazine (or equivalent) daily. Ten patients on this ward undergoing treatment for an acute upset were receiving an equivalent of 1000 mg. Thorazine daily. Twenty-four other chronic problem patients presently on the same ward are being controlled with an average of 600 mg. Thorazine (or equivalent) daily. (There is an incidence of 46% parkinsonisms, akathisia or dyskinesias in this group of 24 patients.)

Medications on this ward are usually given as a liquid concentrate.

SUMMARY

The successful management of an acutely disturbed ward rests in the control of the chronically disturbed and combative pa-

¹ Richmond State Hospital, Richmond, Indiana.

² Prolixin or fluphenazine—Stelazine or trifluoperazine—Thorazine or chlorpromazine.

tients. A regimen utilizing an average of 1700 mg. Thorazine (or equivalent) daily resulted in marked improvement in the behavior and adjustment of 8 "hard core" refractory patients. Multiple attempts by other means had failed to elicit a sus-

tained improvement. An extremely low incidence of side effects was encountered. The question of control of the difficult patient is usually: 1. Which tranquilizer; 2. In what dosage; 3. Over what period of time.

TABLE 1
Treatments Received by Eight Chronically Disturbed Patients

CASE NO.	MAIN SYMPTOMS	TREATMENTS IN PAST WITHOUT SIGNIFICANT IMPROVEMENT	TREATMENT RESPONSIBLE FOR IMPROVEMENT
1.	Combative, loud, profane, and hostile	800 mg. Thorazine for 7 months	Thorazine 1600 mg.
2.	Mute and combative	400 mg. Thorazine and 40 mg. Stelazine for 3 months 800 mg. Thorazine and 30 mg. Stelazine for 3 months 1200 mg. Thorazine and 20 mg. Stelazine for 1 month	800 mg. Thorazine and 15 mg. Prolixin
3.	Hostile, irritable, demanding, and combative	800-1600 mg. Thorazine for 6 months	2000 mg. Thorazine
4.	Disturbed and combative	Series ECT, symptomatic sedation	800 mg. Thorazine
5.	Temperamental combative, and destructive	"Moderate" dosages of Thorazine, Stelazine, and Prolixin, also ECT.	80 mg. Stelazine
6.	Loud, fearful, combative, and hallucinating	1000 mg. Thorazine for 4 months	2200 mg. Thorazine
7.	Uncooperative and combative	1200 mg. Thorazine for 3 months	800 mg. Thorazine and 30 mg. Stelazine
8.	Hostile, uncooperative, and combative	15-40 mg. Stelazine for 5 months also ECT	80 mg. Stelazine

CLINICAL APPRAISAL OF DEPROL

MICHAEL J. KEITH, M.D.¹

I have had extensive experience with Deprol, a proprietary preparation, combining 400 mg. of meprobamate and 1 mg. of Benactyzine. This preparation has been widely promoted as an antidepressant.

With our present interest in the various new antidepressants, it would seem timely to assess the position of Deprol in relation

to the treatment of depressive illnesses. In 2½ years' experience with the use of Deprol, including treatment of at least 150 patients, I have noted no specific antidepressant activity. The only depressive symptoms that it affects are those of anxiety, minor agitation and insomnia.

Deprol is a useful drug in the management of anxiety when some degree of seda-

¹ 745 Graydon Ave., Norfolk 7, Va.

tion is required beyond that experienced with small doses of phenobarbital or meprobamate. A very considerable percentage of patients receiving Deprol will complain of drowsiness. Many patients can tolerate only half a tablet q.i.d., rather than one tablet q.i.d. No specific complications have been noted with the administration of Deprol (other than those noted in the administra-

tion of meprobamate), beyond frequent incidence of sleepiness.

In summary, in 2½ years of usage, Deprol has exhibited no specific antidepressant effect. However, it is useful as an ancillary treatment in certain anxiety syndromes, when a greater degree of sedation is required than is afforded by the milder sedatives and ataraxics.

THE PREVENTION AND TREATMENT OF CHEMICAL PARKINSONISM WITH UK-738

SIDNEY COHEN, M.D.¹

Some psychopharmacologists have considered that the therapeutic and extrapyramidal effects of the phenothiazine series were positively correlated (1). The opinion was expressed early in the use of these compounds that the extrapyramidal syndrome (EPS) should be deliberately elicited during the treatment of the chronic psychoses in order to assure full phenothiazination. Now it appears that the antipsychotic and extrapyramidal components are separable; active phenothiazines with a low incidence of the EPS have been studied (2). In our opinion the EPS is a disturbing, undesirable complication of therapy which should be avoided if possible, or promptly treated when it occurs. The chronic schizophrenic has serious and, to him, unexplicable derangements of perception, ideation and self concept. To impose the strange postural and kinetic aberrations of the EPS seems unwarranted. For this reason the prophylactic use of antiparkinsonian agents was instituted here when large amounts of phenothiazines with a known high incidence of the EPS were employed. Fifty chronic psychotic patients who were to be treated with high doses of prochlorperazine-model phenothiazines, were concurrently given 4 mg. of UK-738 (N-ethyl-nor-tropine-benzhydrylether-hydrobomide)² a day. Forty-four of the group manifested no observable signs of the EPS, six (12%) demonstrated either parkinsonian or mild

dyskinetic symptoms which were controlled in all but one by increasing the dosage of UK-738 to 8-24 mg. daily. A single patient required both decrease of the phenothiazine and an increase in the UK-738 to 32 mg. for satisfactory control. The 12% incidence of the EPS may be contrasted with reported figures of 40-60% (3, 4) following the use of large amounts of perphenazine, trifluoperazine or fluphenazine. When mild akinesias such as muscle weakness and pain are included, this figure approaches 100%.

As a rule the antiparkinsonian medication could be decreased to 2 mg. daily or omitted after the first two months of treatment. In 13 patients attempts to discontinue the UK-738 resulted in the appearance of some facet of the EPS, indicating that suppression of these symptoms was actually occurring.

Seventy-six chronic schizophrenics who had not been treated prophylactically developed the EPS during their course of phenothiazine medication. They were given UK-738 as soon as the neuromuscular manifestations of the EPS became apparent. Dosages varied from 4-32 mg. daily. The drug was well tolerated. In patients receiving the higher doses complaints of dryness of the mouth occurred. All but 12 patients lost their parkinsonian symptoms following UK-738 therapy along with reduction of dosage of the phenothiazine. The 12 treatment failures consisted of those who either continued to have overt extrapyramidal symptoms, or were insufficiently improved by the amount of the phenothiazine they could tolerate.

¹ Psychosomatic Service, GM&S Hospital, VA Center, Los Angeles 25, Calif.

² The UK-738 was supplied by Mr. Harry Alt-house of Sandoz Pharmaceuticals.

Eight patients have been taking UK-738 for more than one year, of these 3 receive 32 mg. daily. This group are "Parkers," that is, they readily develop the EPS on all phenothiazines and appear to require continuous suppression. A single dose of certain phenothiazines can induce dyskinetic movements of the neck and face in 1 patient of this group. UK-738 has produced a complete or sufficiently satisfactory remission in all of these patients.

SUMMARY

In the treatment of the long term psychotic patient who will require large amounts of phenothiazines, especially those with a piperazine ring in the side chain,

consideration should be given to prevention of the EPS. UK-738 has satisfactorily suppressed these disturbing symptoms without adding undesirable side effects of its own. It has also proven to be an effective agent in the treatment of manifest chemical parkinsonism.

A METHOD FOR SERIAL SAMPLING OF BLOOD DURING SLEEP

JAMES L. MATHIS, M.D., BOYD K. LESTER, M.D., AND
CHESTER M. PIERCE, M.D.¹

In order to study biochemical changes occurring in experimental human subjects during unsedated sleep and dreams, a method of withdrawing blood without awakening the subject has been successfully employed at the University of Oklahoma Medical Center during the past year.

Under local anesthesia a number 20-gauge indwelling polyethylene catheter is inserted into the most readily available large superficial vein of the forearm through a 17-gauge needle. The size of the needle obviates the use of smaller wrist and hand veins in most subjects. The catheter is connected to an intravenous extension tube 20 inches in length which is in turn connected to a 3-way petcock taped at bed level to an ordinary intravenous standard; 500 cc. of saline is attached to the petcock through a second intravenous tube. Regulation of the saline drip to approximately 6-10 drops per minute suffices to prevent coagulation in the tubing and yet introduces only 180-200 cc. of fluid in a 7-8 hour period.

After taping the catheter to the arm and

checking the attachments, a small drop of collodion is placed over the venepuncture site. Blood is drawn with a 20 cc. syringe attached to the outlet arm of the petcock. Since the system distal to this petcock contains approximately 4 cc. of saline, this must be withdrawn and discarded before obtaining undiluted blood samples. After obtaining each blood sample it is important to allow saline to flow rapidly for a sufficient time to clear the distal tubing of blood. The rate of flow is then again reduced to 6-10 drops per minute.

Depth of sleep is determined by monitoring an encephalogram tracing throughout the night. Dream onset is shown by deviations of the tracings taken from electrodes glued to the outer canthus of each eye.² Since no sedation is given, obtaining an undisturbed sleep pattern depends upon the system producing a minimum amount of discomfort. The hum of an electric fan is an excellent method for masking incidental noises. Minimal light is obtained by using a rheostat wall switch which controls the light and keeps the room dimly illuminated. These measures permit normal sleep in most cases.

¹ Respectively, Resident in psychiatry; Assistant professor of psychiatry; and Assistant professor of psychiatry, University of Oklahoma School of Medicine, Oklahoma City, Okla.

² Dement, W., and Kleitman, N. : *J. Exp. Psychol.*, 53 : 339, May 1957.

Two difficulties have been found in this procedure. First, a 17-gauge needle demands a very large and stable vein. Therefore, the polyethylene catheter occasionally cannot be employed in subjects with small veins. Second it was found on several occasions that blood could not be withdrawn from the patient prior to sleep, even though the catheter was obviously within the vein as evidenced both by touch and by the free flow of saline. This has been observed even though blood comes easily when the vein is first punctured. In most instances blood again flows readily if the subject is allowed to sleep before the next attempt is made. No clear-cut explanation for this phenomena is offered. Psychological factors, in conjunction with the needling itself, may con-

tribute to a localized venospasm. The fact that blood flows freely after the subject is allowed to relax supports this hypothesis. A change in blood viscosity secondary to anxiety has also been postulated. There have been no untoward after effects or complications of this procedure.

CONCLUSIONS

An indwelling polyethylene tube in a large superficial vein offers a simple, safe, economical technique for obtaining serial blood samples without disturbing a sleeping subject. This permits study of hematological correlates of depth of sleep, diurnal and other periodic changes, and episodes of dreaming.

A CLINICAL EVALUATION OF SKF-6333

RUPERT H. MAY, M.D., THOMAS J. JOYNES, M.D., AND
NORMA D. BYLENGA, A.B.¹

10- [2-(1-methyl-4-piperazinyl)ethyl] -2-trifluoromethyl phenothiazine dihydrochloride² was evaluated as a "tranquilizer" in 17 female psychiatric patients (age: $Mn \pm SE$: 38.5 ± 1.7 years) of the following diagnostic categories: 11 "acute" schizophrenics, 3 manic-depressive psychotics, 3 involutional psychotics, 1 psychoneurotic. Chemically, SKF-6333 is trifluoperazine minus one methyl group in the side chain of position 10. Pharmacological animal experimentation suggested a potency similar to chlorpromazine(1).

The evaluation was "single-blind," since data on human application were not available. Nine of the 17 patients had not responded to other forms of biological therapy during this hospitalization. The indications used were similar to those for chlorpromazine. SKF-6333 was given in a total dosage range of 1,875 to 19,550 mg. ($Mn \pm SE$: $7,960 \pm 1,523$ mg.) over 16 to 129 days (52 ± 8 days), with a highest daily dosage of

15-600 mg. (257 ± 35 mg.).

Thirteen of the 17 patients improved

FIGURE 1

10- [2-(1-methyl-4-piperazinyl)ethyl] -2-trifluoromethyl
phenothiazine dihydrochloride
SKF-6333

¹ From the Cleveland Psychiatric Institute and Hospital, Cleveland 9, Ohio.

² SKF-6333: The authors acknowledge with thanks financial support from Smith Kline & French Laboratories.

sufficiently for release, 4 needed additional ECT. Mental status ratings exhibited a moderate anti-psychotic effect, as seen in decrease of delusions, hallucinations, and hostility. Affect showed changes toward "normalization," by increase when formerly depressed and by decrease when exaggerated earlier. A definite "euphoric" effect was noted, especially in smaller dosages. Stimulation of activity and interest resembled trifluoperazine effects. The improvement was insufficient in very disturbed schizophrenics.

Twelve of the 17 patients showed various degrees of psychomotor restlessness as a side effect, all on a dosage of above 200 mg./day. There were 4 instances of allergic skin manifestations (without accompanying eosinophilia); one other patient not included here, showed a strong skin eruption necessitating discontinuation of the compound after 4 days.

The only changes approaching significance in the physiological and laboratory measurements were: a decrease in WBC

($p < .1$), in eosinophils ($p < .1$), in monocytes ($p < .1$), and, significantly, BUN ($p < .01$). Five individuals exhibited pathological changes in the EKG, not accompanied by clinical symptoms; all changes reversed spontaneously or upon discontinuation of the drug. The EEG's exhibited a tendency to "low voltage fast activity," and 6 EEG's showed changes in the direction of a convulsive disorder. A modification of the Forrest method (2) permitted testing of urinary excretion of this compound and/or its metabolites, but was reliable only in dosage above 300 mg./day.

SKF-6333 is a fairly powerful psychotropic agent, but unfortunately with a higher rate of side effects than comparable phenothiazines.

FACTORS DETERMINING "RUM FITS"

JOHN W. RHINEHART, M.D.¹

"Rum Fits" are commonly understood to be epileptiform seizures occurring in persons chronically addicted to alcohol and presumably related in some way to the addictive state. There have been reports suggesting that the convulsive state is related to withdrawal phenomena (1, 2, 3, 4), but the exact relationship or causal sequence remains unexplained. The incidence is often reported to be around 10% and in a review of 200 consecutive past admissions for alcoholism to Fairfield State Hospital it was determined to be exactly this figure.

In order to investigate the etiology of "Rum Fits,"² 16 bio-socio-psychiatric factors

in alcoholics admitted to a state mental hospital were studied. These factors were: age; sex; race; handedness; ethnic background of patient and parents; physique; presence or absence of acidosis; liver dysfunction; skull x-rays; history of head trauma; length of alcoholism; number of previous withdrawal reactions; diagnosis; and electroencephalogram. The sample consisted of 80 consecutive admissions with a diagnosis of an acute or chronic brain syndrome associated with alcohol addiction, sociopathic personality disturbance, addiction alcoholism, and other diagnoses with secondary alcoholism. Ten patients were excluded because of such factors as chronic metabolic disease, proven pre-alcoholic epilepsy, lobotomy, other addictions, chronic infectious illnesses, or premature discharge from the hospital preventing adequate work-up. IBM cards were utilized in compiling and analyzing

² The advice and encouragement of Dr. D. X. Freedman, Department of Psychiatry, Yale University School of Medicine; and Dr. Jane E. Oltman, Clinical Director, Fairfield State Hospital is gratefully acknowledged.

ing the data. Of the 70 cases, 51 patients fell into a "non-convulsive group" and 19 into a "convulsive group." Fifty of the patients were in the 40-59 year age group; 66 were men, 4 women; 65 white, 5 negro; 51 patients had leptosomic-athletic physiques; 38 had evidence of acidosis (CO_2 alteration below 25 meq/L and positive urine acetone test); 5 had evidence of liver dysfunction (cephalin flocculation in excess of 2+ in 48 h, thymol turbidity in excess of 4 units and prothrombin time in excess of 2 sec. from normal); 56 patients had over a 10-year history of alcoholism; 4 patients had significant abnormalities of skull x-ray; 20 had a history of previous head trauma; 45 had 0-1 previous acute brain syndromes and 25 had more than one. Eleven patients had non-specific EEG abnormalities; 36 had acute brain syndromes (delirium tremens, acute hallucinosis, or pathologic intoxication); 65 were right handed.

The seizures in the convulsive group were consistently generalized grand-mal in type except for one patient who experienced right-sided Jacksonian seizures; they generally occurred within 0-48 hours after being jailed or hospitalized. Each patient had only one seizure except for 2 patients with 3 and 3 plus consecutive seizures. Eight patients experienced convulsions without the development of delirium tremens; 11 patients had associated delirium tremens and in 6 of these it appeared to follow the convulsive seizure. In 4 the temporal relationships were impossible to determine, and in 1 it occurred in the early phases of the delirium.

In comparing the data in the convulsive group against those in the non-convulsive group, there were no significant or preponderant findings. Neither physiologic imbalance nor the sociopsychiatric factors singly or in combination could be seen as related to the occurrence of seizures. The most apparent difference was in the greater incidence of abnormal EEG in the convulsive group (6 in the 51 non-convulsives and 5 in the 19 convulsives) but this finding was not statistically significant. In addition, the 6 patients with abnormal EEGs in the non-convulsive group showed no striking difference in the other factors from the 5 with abnormal EEGs who had

convulsions.

Though it is often stated that "Rum Fits" commonly initiate or at least are a part of the withdrawal reaction from alcohol, the exact reason why some chronic alcoholics are vulnerable to their occurrence remains obscure. We can only guess that there is some multi-faceted interaction of structural and physiologic events that lies beyond the rather gross and obvious characteristics that were investigated here.

More specific, detailed studies appear to be necessary and our experience reflects the need for a controlled research situation where all variables (particularly the sequence of physiologic events during both active addiction and withdrawal) can be as carefully examined as possible.

CONCLUSIONS

1. A 10% recorded incidence for "Rum Fits" in an alcoholic population was determined by review of the charts of 200 consecutive patients admitted to a state mental hospital. This is in essential agreement with other published data, though it is felt that if patients are more closely studied, the incidence is somewhat greater, as seen in the sample for the second part of the study.

2. In a preliminary investigation of 16 bio-socio-psychiatric factors, it was found that none of them singly or in combination, significantly differentiated those alcoholic patients who had "Rum Fits" from those who did not. A more controlled research situation was seen to be necessary in order to more closely study the variables of the addictive and withdrawal phases of alcoholism.

A CONTROLLED STUDY OF HALOPERIDOL : THE EFFECTS OF SMALL DOSAGES

ARTHUR S. SAMUELS, M.D.¹

Haloperidol,² which is a 4'-fluoro-4-1-(4-hydroxy-4-(4'-chloro)-phenylpiperidino)-butyrophenone, has recently been introduced in Europe as a promising tranquilizing agent. Its interest to us lies in the fact that it is chemically unrelated to any medication used in this country but is reported to have both therapeutic effects and side effects similar to those produced by the phenothiazines. Previous reports (1, 2) have noted the severity of extrapyramidal and other side effects with higher dosages. The purpose of this study was to ascertain the clinical effectiveness of this drug at dosages below those at which troublesome side effects are usually encountered.

Employing a carefully controlled double blind procedure, we administered the medication to 26 inpatients (on the Tulane Psychiatric Service at the Charity Hospital of Louisiana in New Orleans). This report is on the 20 of those who fulfilled our control group requirements. This group includes 10 schizophrenics (5 acute paranoids, 3 acute undifferentiated, 1 chronic paranoid, and 1 chronic simple type), 1 acute paranoid reaction, 3 psychotic depressive reactions, 1 anxiety hysteria, and 2 patients who demonstrated mixed organic-schizophrenic symptoms. There were 12 females and 8 males, ranging in age from 13 to 55 years. Six of the patients had had previous psychotic episodes. The nature of the precipitating factors for the present psychosis was severe in 1 case, moderate in 5 cases, and mild or unknown in the other cases. The overall duration of treatment varied from 2 weeks to 3 months with the controlled study including 2 weeks on drug and 2 weeks on placebo for each patient. Dosage was by mouth, usually 1 mg. b.i.d. the first week and 2 mg. b.i.d. the second week. Mental status evaluations, employing a scale described elsewhere (3) were performed weekly by the author.

RESULTS

Estimating overall improvement following 2 weeks of therapy with R.1625, 8 patients showed improvement with their symptoms subsiding completely; 8 showed definite improvement but were still seeking further relief from their symptoms; 2 showed only slight improvement with benefits not great enough to warrant further use of the drug; and 2 showed no change. These results were slightly better than those obtained by a matched control group receiving placebo only, but the difference between these two groups was not statistically significant. On the other hand, using the patients as their own controls, an improvement which was statistically significant at the 1% level was found when the patient's response to the drug was compared with the same patient's response to the placebo.

Changes in the severity of the following symptoms were recorded on a 4-point scale: disorder of affect, association defect, depersonalization, depression, anxiety, delusions, hallucinations, and social withdrawal. In only two of these, anxiety and social withdrawal, did the improvement show up as statistically significant (at the 5% level of significance) as compared with the improvement of the group on placebo. In 2 cases of severe paranoid schizophrenia dramatic improvement was seen, with marked reduction or disappearance of symptoms within 24 hours after the patients were switched from placebo to drug.

Improvement, when it occurred, became evident 24-48 hours after drug therapy was begun. Three patients showed definitely more improvement when they were receiving 2 mg. b.i.d. than on 1 mg. b.i.d. Higher dosages for longer periods were tried with a few patients, but no increase in benefits was noted.

Five of the patients in our group reported overwhelming sleepiness while taking 2 mg. b.i.d. They preferred to stay in bed and sleep most of the day, but could be easily

¹ Dept. of Psychiatry and Neurology, Tulane University School of Medicine, New Orleans, La.

² Supplied as R1625 by the G. D. Searle and Co.

aroused. This side effect was much less severe on 1 mg. b.i.d., and actually caused discomfort in only 2 cases at the lower dosage. There were no extrapyramidal side effects at the dosage levels employed, aside from a twitching of the masseter muscles in one case. No significant changes were noted in blood pressure, pulse, weight, temperature, CBC, liver profile or urinalysis.

SUMMARY

The clinical effects of Haloperidol in dosages small enough to avoid troublesome side effects were observed in a small, care-

fully controlled study. The overall beneficial effects noted were inconclusive statistically as compared with placebo, although there was a significant reduction of anxiety on the drug. More extensive evaluation of this compound is indicated.

CLINICAL TRIAL WITH CYCLOPENTIMINE

L. SCHWARZ, M.D., T. BAN, M.D., AND R. SMITH, M.D.¹

Published reports on cyclopentimine² have described it as "a well tolerated anti-anxiety, antipsychosis agent"(1). The only side effect reported in a few patients has been nausea, which subsided promptly with reduction of the dose or when antihistaminics were added. The patients on the drug displayed an unusual willingness and interest in receiving the medication, and expressed a subjective feeling of well-being(2).

Based on these findings, we carried out a clinical trial of the drug with 30 hospitalized psychiatric patients. A limited response to previous treatment and absence of physical pathology were the only criteria of selection.

The diagnostic distribution of our subjects was similar to that reported by the other authors and we administered the doses in the dosage range suggested by them and by the manufacturer. The following table gives the diagnostic distribution of our sample group:

Schizophrenic	27
Psychotic depressive reaction	1
Involuntary psychosis, paranoid	1
Mental defective with psychosis	1

Mean age was 50 years, with a range of 21-63. Their hospitalization ranged from 2-26 years, giving an average of 20 years.

Preceding the trial period the patients' previous medication had been discontinued for 1-4 weeks. The subjects were put simultaneously on 1000 mg. of Cyclopentimine in 4 divided doses. This was increased to 2000 mg. in the second week and 3000 mg. in the third week. It had been planned to maintain a dosage of 3000 mg. q.i.d. administration until the end of the 10th week.

RESULTS

Within one week 19.8% of the patients were vomiting, 16.5% were nauseated and 70% had lost 1 to 5 lbs. in weight. Nausea and vomiting started immediately after the first dose of the drug and could not be suppressed by an antihistaminic agent (Diparalene).

At the beginning of the second week all the patients were placed on preventive Diparalene. However the percentage of the vomiting patients increased to 52.8% by the end of the week, and to 62.7% by the end of the third week, and an additional 13.2% were nauseated.

In combination with nausea and vomiting, insomnia occurred. In the first week 11% of the patients slept only 6 hours. In the second week this increased to 28% and in the

¹ Verdun Protestant Hospital, Montreal, Que.

² The cyclopentimine used in this experiment was supplied through the courtesy of the Abbott Laboratories, under the trade name of Cypentil.

third week to 34%. With such severe side effects the patients did not feel well and were reluctant to take the medication.

Other side effects of lesser importance were: extrapyramidal symptoms in 3 subjects, headache in 3 and dermatitis in 2.

Because more than 75% developed side effects and because of the severity of the nausea, vomiting, weight loss and insomnia, the drug trial was discontinued after the third week.

Psychiatric evaluation showed that 8 patients had improved, 20 remained unchanged and 2 had become worse.

One of the improved subjects was well enough to be discharged. This undifferentiated schizophrenic patient had presented paranoid trends with depressive mood changes (at the beginning of the drug trial).

In all 8 improved patients the beneficial effects were manifested in decreased aggressiveness, and in mild euphoria.

SUMMARY

A clinical trial was conducted on 30 hospitalized female patients with cyclopentimine. Decreasing aggressiveness and euphoria were observed as beneficial effects in 8 patients.

However, because of the uncontrollable side effects of severe nausea, vomiting, loss of weight and insomnia, as well as extrapyramidal symptoms, headache and allergic dermatitis, the trial had to be discontinued prematurely.

It seems that these severe side effects at the present time overshadow the compound's potential therapeutic value.

A UNIQUE MONOAMINE OXIDASE INHIBITOR FOR DEPRESSION

LUIGI BUCCI, M.D., AND JOHN C. SAUNDERS, M.D.¹

N-Benzyl-N-methyl-2-propynylamine (Mo-911)² is a new potent monoamine oxidase inhibitor both *in vitro* and *in vivo*. Authoritative opinion is sufficient for many writers to continue to challenge the role of the monoamine oxidase system in diseases of affect. Studies of iproniazid indicate that its irreversible inhibition may be the result of dehydrogenation at the active site of the enzyme. Preparation MO-911 with its triple bond provides an active site of formation for the enzyme complex. It also differs chemically from the previously tested preparations in that it does not contain a hydrazine or a carbonyl radical. Both of these groups introduce high activity sites in the molecule and are known to react with enzyme systems other than monoamine oxidase, specifically, many of the pyridoxal

enzymes. These radicals possibly account, in part, for the untoward effects of these drugs in man. This study adds confirmatory data to support a hypothesis of one of us that monoamine oxidase has an essential role in depression and other diseases of affect(1).

This preliminary report is on 25 female patients from an admission service. They were selected for their primary signs and symptoms (phenomenologically); however 3 patients were classified as depressives, 1 manic-depressive, and the remaining 21 were schizophrenics (3 with a history of alcoholism) characterized by autism, anergy, flatness of affect and depression. The secondary symptoms, delusions and hallucinations, of schizophrenia could not be elicited but contact with reality was lacking. Their ages ranged from 20 to 61 years; however, 21 were in their 30's. Three patients were hospitalized for over 3 years, 5 patients had more than one admission and had been ill for 2 to 3 years and the re-

¹ Research Facility, Rockland State Hospital, Orangeburg, N. Y.

² Preparation MO-911 (N-benzyl-N-methyl-2-propynylamine) was supplied by Abbott Laboratories, North Chicago, Ill.

maining 17 were first admissions. Previous psychopharmacological therapy had been given to 18 patients, 1 had received imipramine and 17 had received phenothiazines. Response was far from satisfactory, therefore these patients were given MO-911 for alleviation of the primary symptoms of their psychoses.

Patients were started on 25 mg. t.i.d. of MO-911 which was found to be effective in 22 of 25 patients. In the 2 who failed to respond, the dose was increased to 50 mg. t.i.d. without further clinical effect. Amelioration of depression is usually obvious within the third week of therapy. Patients become more alert and responsive, develop interest in personal hygiene, initiate activities on the ward and become interested and better integrated in their environment. Analysis of the 25 patients receiving MO-911 demonstrates that it was clinically effective as 11 have been released, 4 are improving and will probably be discharged in the near future. There was no change in 2 and a paranoid schizophrenic became worse (agitated, confused and incoherent). The remaining schizophrenics are free of their autism and depression and now we have added a tranquilizer in order to alleviate their secondary symptoms. The clinical efficacy of MO-911 as an antidepressive agent

is highly effective in depression and in schizophrenia where autism, flatness of affect and anergy characterize the patient.

This monoamine oxidase inhibitor did not produce delusions or hallucinations during this study as is occasionally observed with the hydrazines or imipramine. There was no postural hypotension, edema, ataxia, color blindness, jaundice, neuritis or constipation. One patient had an insatiable thirst and laboratory studies revealed she was not a diabetic. Clinical laboratory studies of peripheral blood, urine and liver function were always within the normal range during this 8-month study.

In conclusion, our preliminary studies indicate that MO-911, which represents a new chemical class of monoamine oxidase inhibitors, is therapeutically one of the most effective antidepressive agents available. The apparent absence of toxicity and side effects are probably due to lack of the hydrazine and carbonyl moieties on the MO-911 molecule. This monoamine oxidase inhibitor fulfills the requirements of a practical antidepressive drug in man and warrants widespread clinical usage.

THE USE OF STELAZINE AND PARNATE IN CHRONIC, WITHDRAWN PATIENTS

ALFRED H. VOGT, M.D.¹

Previous reports(1, 2) have evaluated the usefulness of Stelazine and Parnate² in chronic, withdrawn, mental patients. This study was designed to further evaluate these drugs with the same type of patient but more particularly to use relatively high dosage of Stelazine in connection with manufacture's recommended dosages of Parnate. Fifty chronic patients were selected from a white male population. These patients had all previously been extensively

treated with tranquilizers and/or E.C.T. Most had been ill for 5 years or longer. The overall age was 40 years. Diagnostically they consisted of:

TABLE 1

Schizophrenia, all types	39
Manic-depressive psychosis	1
Mental defective with psychotic reaction	3
Organic brain syndromes, all types	4
Severe personality disorder	3
	50

¹ Houston State Psychiatric Institute, Texas Medical Center, Houston, Texas.

² Parnate was provided by Smith Kline and French Labs.

Despite the variations in diagnosis, all showed primary and secondary symptoms

of the schizophrenias. All were socially and symptomatically seriously ill.

These patients were initially removed from all medications for 2 weeks, during which they were physically examined and given an extensive mental status. Base line laboratory data were obtained. After 2 weeks of observation Stelazine was started on all patients. The starting dosage was rapidly elevated to 20 mgs. b.i.d.

Another evaluation period of 2 weeks was carried out during which time the dosage of Stelazine was adjusted to an individualized maximum amount. Side effects were noted: 18 patients developed extrapyramidal symptoms. In each case Artane controlled these side effects in conjunction with a reduction in the dosage of Stelazine. After 2 weeks on Stelazine, Parnate and placebo were given to 2 groups on a double blind basis. The study period was 3 months. During this time observations were made to determine social performance and symptomatic improvement; the ward programs were held as constant as possible.

RESULTS

All patients were improved after the first 2 weeks of treatment with Stelazine in both social and symptomatic areas. An analysis

TABLE 2
Stelazine-Parnate Group

SOCIAL AND SYMPTOMATIC		PLACED ON LEAVE	
Much improved	6	5	(1 return)
Improved	13		
No change	5		

Stelazine-Placebo Group

SOCIAL AND SYMPTOMATIC		PLACED ON LEAVE	
Much improved	8	7	(1 return)
Improved	10		
No change	8		

of the results at the end of the study are shown in Table 2.

None of these 50 patients suffered hypotension, liver dysfunction, or dyscrasias, once an optimal individualized Stelazine dosage was obtained. Of the 18 patients receiving Artane 11 were in the Parnate group, 8 developed extrapyramidal signs after Parnate was started.

DISCUSSION

It seems that Stelazine is the more active and significant agent accounting for the improvement of these patients. It also seemed that when the Parnate was added (30 mg./day) it amplified the extrapyramidal side effects of the Stelazine in certain cases. In general, symptomatic improvement was greater than improved social performance whether on placebo or Parnate. It was curious to note that when the Parnate ran out many patients complained about not receiving their medication. However, this is hard to evaluate because there was some enthusiasm regarding the idea of being in a "project." All patients, whether on Parnate or placebo, seemed more willing to work and carry on ward life. This attitude has persisted despite the ending of the "project." The overall conclusion is that Stelazine and Parnate combined may give a slight edge in the activation of a chronic, apathetic, withdrawn patient over Stelazine alone.

The rarity of serious side effect (except the extrapyramidal signs) was encouraging regarding the safety of higher dosage of Stelazine.

CASE REPORTS

CIRCULAR MANIC-DEPRESSIVE REACTION MODIFIED BY "PROPHYLACTIC ELECTROSHOCK"

DONALD W. HASTINGS, M.D.¹

Manic-depressive reaction of the circular type presents one of the most difficult problems in psychiatry both to patient and physician. This case is deemed of reportable interest because it represents a reasonably successful control of this serious illness by the "prophylactic electroshock" (EST) method described by Geoghegan and Stevenson.²

The patient is a professional man of 56, married, three children. He was an only child. His father also had manic-depressive reaction and has been under my care for two depressed episodes and on one occasion both father and son were patients simultaneously on the same ward of this hospital.

The patient's normal personality is best described as obsessive-compulsive. He is meticulous, has a place for everything and everything in its place, has rigid control over feelings of anger but "boils inside," pays a great deal of attention to money, *etc.*

His first attack was a depression which occurred in 1929 (age 24). This lasted about 4 months. The next attack came 10 years later (1939, age 34) and was another depression. He was hospitalized elsewhere for this attack and during its 6-month duration he received 13 typhoid shots, 7 metrazol treatments, and a course of insulin shock therapy (depth and duration unknown). He was depressed again in 1940 (age 35) and made a suicide attempt with barbiturates. In 1944 (age 39) he was hospitalized again for depression with no known shock therapy. Immediately after the conclusion of this attack, again about 6 months, he went into a hypomanic episode which required hospitalization and lasted about 8 months. He had nine EST treatments at this time. This marked the onset of the definite circular form of the disease and since that time he has never been completely free of illness as will become clear. The depressed attacks have

averaged 6 months, the elations about 8 months. An interesting feature of this man's cycling has been the extremely short period between attacks. Never more than a day or two, it has been at times a matter of minutes. On one occasion he reported passing from 8 months of elation into what turned out to be 6 months of depression while eating dessert one Thanksgiving Day.

I saw him first (April, 1946) at the end of a hypomanic attack. Between that date and May, 1948, I saw him through continuous illness of one phase or another, and he required hospitalization during the worst of two hypomanic and one depressed attacks. During these hospitalizations he received a total of 29 ESTs.

At the APA meeting of May, 1948, Doctors Geoghegan and Stevenson reported on their experiences with "prophylactic EST". The patient was in the hospital at this time recovering from a hypomanic attack. I discussed this treatment with him on my return and he elected to try it. For the next 5 years (1948-1953) he received EST on an outpatient basis at approximately monthly intervals although it was closer to 8-week intervals for the final years (see chart). During this 5-year period he continued to cycle as before, but the amplitude

Chart shows relation between course of illness and "Prophylactic Electroshock"

¹ Department of Psychiatry and Neurology University of Minnesota Medical School, Minneapolis 14, Minnesota.

² Geoghegan, J. J.; and Stevenson, G. H.: *Am. J. Psychiat.*, 105: 494, Jan. 1949.

of the swings was markedly reduced, to the point where one would not have detected the pattern readily unless the patient had factually reported how he felt. At no time during the years 1948-1953 of "prophylactic EST" did he require hospitalization, and he continued throughout this period in an active and successful professional life. It is interesting to note that this man carried an extreme apprehension of convulsive therapy dating back to his metrazol experiences (1939). This apprehension mounted with each succeeding EST during these years until about 1952 it was deemed prudent to treat him in the hospital operating room under general pentobarbital anaesthesia. This practice has continued to date. He feels slightly less anxious under these circumstances although still has fear bordering on panic for 24-48 hours before each treatment.

In April, 1953, after 5 years of "prophylactic EST" with the results stated, both the patient and I raised the question of how long we should continue. He had had 39 ESTs in this series, not counting a total of 7 metrazol, 38 EST, and a course of insulin shock in the years prior to 1948. Because there were no particular guide lines to follow and after correspondence with Dr. Stevenson, it seemed prudent to let this highly intelligent professional man make his own decision, since by this time he was in truth an authority on manic-depressive disease and its treatment. He elected to stop and see what happened.

In October, 1953, it was necessary to hospitalize him again for a severe hypomanic attack which had begun to be crippling about 6 weeks before. He was treated with an EST series (6 treatments in 11 days) and went into remission. We did not re-start the prophylactic EST subsequent to this attack largely because of his severe anxiety about the treatments and because I was interested in seeing if the old circular pattern was still in force. It was. By March, 1954, he was seriously depressed, had to be rehospitalized in mid-June, and received a series of 7 ESTs which produced remission. With these two hospital experiences in mind, we both saw there was no alternative to starting the routine again and began the next 5-year EST series on August 1, 1954. Again the amplitude of the swings was markedly reduced, he continued to practice his profession, and all in all was leading an active useful life with very little interference from the basic illness.

In 1956 an interesting phenomenon occurred which represents the only period of failure of the method. By late June, 1956, he became quite depressed in spite of the prophylactic

EST. (Examination of the chart indicates that ESTs were spaced quite far apart before this attack.) In September, 1956, he was readmitted to the hospital, had 6 ESTs, went into remission, and the prophylactic EST was continued, again with successful outcome, until April, 1959 (a total of 54 more ESTs since stopping the first 5-year series). At this time we again elected to stop. The main reason was that there might now exist the possibility of chemical control of both the elations and depressions. Neither of us by this time had any doubts that the illness would reassert itself in its previous force on stopping the prophylactic EST; rather, could we control it with the newer drugs now available? This proved in part to be the case in the hypomanic episode which started soon after. An average of 800 mg. per day of thioridazine (Mellaril, Sandoz), drug number 1 on the chart, cut down the hypomanic intensity so that he was able to stay at home although it was touch and go, and there were several occasions when his wife felt he would have been better protected in the hospital. The patient felt rather dulled by the drug. He cycled into depression in mid-August of 1959, and then began a trial of the new anti-depressant agents.

Between September, 1959 and April, 1960, four of the common agents then available were tried for approximately 4 weeks each: iproniazid (Marsilid, Roche), phenylethylhydrazine (Nardil, Warner-Chilcott), nialamide (Niamid, Pfizer), and imipramine (Tofranil, Giegy), drugs 2, 3, 4, and 5 on chart. None of these altered his depression in any noticeable way. He continued to work sporadically during this time although on a reduced schedule and with frequent days away from the office. By late May, 1960, the depression had passed and he was again hypomanic, and again he rode out this attack at home with thioridazine alteration. The hypomanic phase terminated in November, 1960, and was abruptly replaced by a retarded depression of such severity that he required hospitalization. He was at this point started on a trifluoperazine-tranlylcypromine combination (Parstellin, SKF), drug number 6 on chart, which we were using experimentally and the dosage was raised to 9 mg. and 90 mg. of each respectively. After about 3 weeks on these drugs the retardation seemed to lift somewhat, and he felt enough improved to return home. However, in retrospect the improvement was probably largely due to the sanctuary of the hospital than to the drugs because shortly after his discharge he reported that he was not at all well. Still continuing on these drugs, he desperately tried to push his

way through the depression at home, but by the middle of February, 1961, it was apparent that he could not continue and he was readmitted on February 26, 1961, in a severely retarded depression. Stopping these drugs (No. 6) at this point did not seem to alter the illness in either direction. He received 9 ESTs and was discharged much improved on March 27, 1961.

The patient has elected to start another 5 years of prophylactic EST feeling in retrospect that the only relatively "well" years he has had since 1943 were the periods of 1948-1953 and 1954-1959. He feels that the various anti-depressant agents did nothing in his particular case and that while the chemical alteration of the hypomanic phases was useful, it was not as satisfactory as the prophylactic EST alteration.

To date this man, now 56 years of age, has had 147 chemically or electrically induced convulsions spread over a 20-year period. He has had the usual temporary memory deficit after each closely spaced series of EST but has had little trouble with memory disturbance subsequent to each of the ESTs spread at the monthly or greater intervals (1948-1953 and 1954-1959). He has had no instance of convulsions or convulsive equivalents during this period (except those medically induced) nor does he have any neurological evidence of central nervous system abnormality. His general physical status and laboratory studies have remained within normal limits.

COMMENT

In this particular patient with circular manic-depressive illness, two 5-year series of prophylactic EST have been quite effective in controlling the amplitude of manic and depressive phases. Stopping the treatment at the end of the first and second 5-

year series saw the illness reestablish itself with its previous severity within a few months. In spite of the amount of convulsive therapy this patient has had, there is no clinical evidence of brain damage. This amount of convulsive therapy has done nothing to alter the basic manic-depressive process since it quickly reestablishes itself once treatment has been stopped. Five "anti-depressive" drugs were ineffective in altering the course of his depressive phases. Thioridazine was helpful in controlling the hypomanic phase.

This patient is unique in a number of respects but in one above all others, *i.e.*, he has had the courage to follow through with a long term treatment program when each EST produced fear bordering on panic. My experience with prophylactic EST in similar cases has been that most patients are unable to follow through with this long a regimen because of the fear of treatments which develops. Although we routinely use pentobarbital anaesthesia-anectine modified EST in which the only unpleasantness for the patient is the needle stick for the anaesthetic, this has not seemed to reduce patients' growing fears of treatments to any extent. Almost all patients report that so much fear is illogical, that they know they are in good hands, *etc.*, but the fear persists. It is probably the unusual person who will come to the hospital each month in spite of such fear, especially when he feels quite well. The power of rationalization, to regard the illness as a thing of the past, is too strong. If medals were awarded for this sort of courage, the patient described would qualify for one with four clusters.

ACUTE INTERCURRENT PSYCHOSIS DURING THE COURSE OF FAMILIAL PERIODIC PARALYSIS¹

IRWIN M. GREENBERG, M.D.²

The patient to be described was brought to the attention of the psychiatric consult-

¹Adult Psychiatry Branch, National Institute of Mental Health, National Institutes of Health, Public Health Service, U. S. Department of Health, Education and Welfare, Bethesda, Maryland.

²Now at Hillside Hospital, Glen Oaks, New York.

ant because of the sudden onset of grossly psychotic behavior during the course of a long hospitalization for research purposes. The literature on familial periodic paralysis has revealed no other such cases. Aird(1) states that no clinical psychiatric changes can be discerned, and Straus(5) cites the

good social adjustment of the patients. Both imply that the patients do not encounter emotional difficulties, and appear to attribute this fact to the absence of cerebral pathology. Shy(4) also maintains that psychiatric symptomatology must be considered a complication of exogenous etiology during the disease, and not a primary manifestation. Two cases of mental deficiency in children have been reported, however. Couston's(2) case was that of a child believed to have familial periodic paralysis as well as seizures, but without a family history of paralytic phenomena. The only suggestive familial symptoms were of migraine headaches in the boy's mother and paternal grandmother. Another case reported by Prader and Zellweger(3) was a 7-year-old boy with a dystrophic adiposogenital syndrome. The authors believed his primary lesion to be an adrenal cortical tumor or a hypophyseal disturbance. This boy did not have the familial form of periodic paralysis, but another potassium-losing lesion which produced periodic paralysis. Shy(4) was of the opinion that he probably had primary aldosteronism.

The following case is that of a patient who suffered from a psychotic episode during the course of familial periodic paralysis, and who also had chronic emotional difficulties related both to his organic illness and to his personality structure. This report will deal only with the patient's acute psychotic episode.

Chief Complaint: The patient was a 28-year-old, Caucasian Protestant laborer, of native birth, who absented himself suddenly from the hospital, without informing the clinical personnel. He was returned to the nursing unit by ambulance from a hospital in a nearby city, and when interviewed by his physician, was unable to recall having been on the unit previously, called himself by another name, was experiencing auditory hallucinations, and appeared generally confused. Emergency psychiatric consultation was then requested.

Presenting Illness: Interviews with the nursing personnel and with the patient's physician revealed that 5 days prior to his elopement, he had lost his position as timekeeper for a firm in the neighborhood because of a past criminal record. The patient had become attached to his position and to his fellow workers, and became noticeably depressed when

he lost the job. The next day, he solicited a ride on a passing truck to his home, which was about 100 miles from the hospital. He visited his family and returned the next day in the same manner. On the following day, he left the hospital without permission, with the intent of going to a nearby city to repay a debt. Upon encountering some old acquaintances, the patient began a bout of prolonged alcohol ingestion and was discovered by the police, wandering the streets and hallucinating. The patient was taken to another hospital and then returned to the nursing unit by ambulance.

Past Personal History: The patient's past history revealed that he had first become ill at 4 years, and felt deprived because he could not participate in ordinary activities. He was in the Armed Forces for a few months until his illness was discovered, and then given a medical discharge. He was also treated with penicillin for a positive blood serology while in the Armed Forces. On one occasion, he was convicted of stealing an automobile and was placed on parole during the course of his hospitalization.

Psychological evaluation in prison had been done, and the diagnosis of sociopathic personality disorder had been made. A prison report described the patient as seclusive, and implied that he used his illness as an excuse for lack of success. On one other occasion, while in the hospital, the patient had disappeared overnight and returned suddenly. He had gone to the same nearby city impulsively. The episodes of automobile stealing were later described by the patient as essentially impulsive acts.

The patient had done a good deal of traveling about the country, had not finished high school, and worked at odd jobs for varying periods of time, never for more than 2½ years.

Family History: The family history was meager. The patient was the fifth child in a family of seven, with three brothers and three sisters. One brother, one sister, and his father also suffered from familial periodic paralysis.

The patient's father was interviewed by one of the ward physicians, who described the father, an electrician, as a short, weak and overbearing man. The physician felt that the patient's difficulties could be understood in terms of the father's emotional aloofness and authoritarian manner.

Course: At the initial interview, the patient was acutely agitated, was pacing his room, and stated that he had to walk to St. Louis. He called himself by another name, R., and said that if he could only walk to St. Louis,

everything would be all right. He was having auditory hallucinations, was disoriented for time, place and person, and did not recognize any of the nurses or physicians, whom he had known for 14 months. There was no recognition of the possibility that his behavior or feelings were unusual. He felt that he had to obey the voice he heard telling him to walk to St. Louis.

Blood was drawn to evaluate bromide and barbiturate levels, which were normal. Thyrotoxic crisis was excluded by a normal protein-bound iodine value, determined from a recently drawn blood sample. The basal metabolic rate and electrolytes were also of normal value. Blood serology was negative.

Heavy doses of chlorpromazine were instituted and the patient was seen daily by the consulting psychiatrist for the next month. The nursing staff was carefully instructed in the care of the patient, an attendant was with him at all times, and occupational therapy was instituted.

Within one week, the patient remembered his name and began recognizing ward personnel. He still heard voices, and maintained that the voice of his conscience was speaking to him. He was noticeably depressed, and wanted to leave the hospital. R. was the name of a deceased friend whom he had last seen in St. Louis, together with a deceased girl friend whom he felt he wanted to see once more. The patient also began remembering the deaths of some people who had been important to him in recent years.

Psychological testing was done during the following week.³ The psychologist's summary was: "The tests show S, with an average vocabulary, to be at the upper end of the 'normal' range (I. Q. 108). Had he not been so heavily sedated during the initial session, he might well have tested slightly higher, classifying as 'bright normal.' The drawing he produced is more like those done by organics than by schizophrenics. It suggests his rejection of his paralyzed legs and his virility strivings. The Rorschach is very impoverished and stereotyped, again more organic than schizophrenic, and indicative of profound emotional repression. The TAT stories reflect some aspects of his upbringing, particularly the element of parental domination, no doubt enhanced by his infirmity, from both of which he seeks escape. Unfortunately, his escape fantasies lead him into alcoholism and into aggressive anti-social behavior. While it is true that he has recently

had a dissociative episode and been hallucinated following a drinking spree, I find no evidence in the tests of schizophrenic thinking. There is probably mild, underlying organic pathology but the main problem from the personality standpoint is his psychopathic behavior and his psychopathy I would consider secondary to his illness, not primary."

Other findings included a "repression of affective life" on the Rorschach test, and several TAT stories with the theme of loss and subsequent grief.

The patient improved during his final month in the hospital. He continued to be depressed, but stopped hallucinating and became completely oriented. The dosage of chlorpromazine was gradually decreased. He was discharged to his family and arrangements were made for him to have psychotherapy in his home community. Several months later, he was again arrested for stealing an automobile.

DISCUSSION

Some of this patient's difficulties appear to bear a direct relation to his organic disease process. His wish to walk to St. Louis appears to be in keeping with the fact that exercise early in the course of an episode can abort an attack of familial periodic paralysis. It is also not surprising that a person with a diseased muscular system and a domineering father would choose to steal an automobile in an attempt to express his manliness and independence. The intense separation anxiety as evidenced by his depression and several of the TAT stories can be understood if one imagines a 4-year-old boy suddenly unable to move or to defend himself.

The discrepancy between the psychological test findings of organicity and the absence of organic cerebral pathology in patients with familial periodic paralysis (1, 4, 5) can be explained as follows: any patient with a chronic, organic, incapacitating disease will show evidence of that disease on any kind of psychological examination. Whether the cause of paralysis be of central or peripheral nervous system origin, or of muscular or metabolic origin, the patient perceives the final result of paralysis. The body image and self-image concepts are then altered in response to the paralytic episodes, and modified by the patient's other personal experiences. It is these altered concepts which appear on the psychological

³ The author wishes to thank Isabelle V. Kendig, Ph.D., of the Laboratory of Psychology, National Institute of Mental Health, for her invaluable assistance in testing the patient.

tests as evidence of organic pathology. "Repression of affect," similarly, can occur as a reaction to, rather than as a consequence of, organic disease. Hence, the preponderance of organic-like signs of the psychological tests need not be taken as evidence of organic brain pathology, but rather as the psychological reaction to repeated episodes of muscular weakness and paralysis.

Although there was considerable alcohol ingestion, possibly prior to the onset of the hallucinations, the time required for recovery was unusually long for an acute alcoholic psychosis. Furthermore, there was clear evidence of unrealistic behavior unrelated to alcohol ingestion in the patient's sudden elopement from the hospital. In view of the absence of schizophrenic signs on the psychological tests, the clinical diagnosis was that of a functional acute psychotic episode in a person with concurrent familial periodic paralysis and a sociopathic behavior disorder.

SUMMARY

The literature on familial periodic paralysis has revealed no cases of intercurrent psychosis. The patients have been described

by several authors as being relatively free of emotional difficulties, and this freedom has been attributed to the absence of cerebral pathology. A case is presented in which there was an acute psychotic episode during the course of familial periodic paralysis. The patient also had a sociopathic personality disturbance. Psychological test findings are presented, as well as the course of the psychosis. The relation of the patient's psychiatric symptoms and psychological test results to both his organic illness and his personal history is discussed.

RESTRAINT

Psychiatry would be wise to refrain from expressing an opinion on any subject, unless the subject matter is clearly within the realm of psychiatry. In other words, an individual psychiatrist, or psychiatrists collectively through the American Psychiatric Association, should not advise upon any topic unless clinical experience or scientific research has accumulated a relevant body of information, adequate to support the advice.

The public has a right to expect that a psychiatric opinion will be an expert opinion. Advice which is based merely on the convictions of an individual psychiatrist is likely to mislead the public, who will assume that it is an expert opinion based upon the collective knowledge of psychiatry.

An illustration is found in the public debates about the abolition of capital punishment. There is some evidence that capital punishment does not have the deterrent effect assumed by its proponents. Evidence of this nature has not been gathered by psychiatrists and does not belong in the realm of psychiatry. It is doubtful that psychiatry has anything to contribute to a debate about capital punishment.

On the other hand, there are many public issues to which psychiatry can make a contribution, by giving an expert opinion based upon the special knowledge inherent in the practice and science of psychiatry.

The legal rules governing criminal responsibility provide an apt illustration. These rules are not the prerogative of psychiatry—they are distilled from the knowledge of many disciplines. The ultimate responsibility for their formulation rests with the legislature. Psychiatry plays a leading role in the formulation of the tests because it is in a position to provide factual information and expert advice.

The same may be said of the role of psychiatry in relation to legislation governing the sex offender. At present, it is possible for a psychiatrist to make a reasonably accurate prediction of the outcome in a particular case. Even more accurate prediction tables should be forthcoming in the near future and they are bound to have an impact on some of the unnecessarily harsh, punitive laws now in existence. Likewise, psychiatry can put forward concrete, specific proposals in relation to such topics as juvenile delinquency, therapeutic abortion and sterilization.

The climate of public opinion is favourable to psychiatry. Psychiatric opinion is accorded a respectful welcome in most forums. This attitude may well change to scepticism if psychiatry does not practise restraint and refuse to enter into a discussion of controversial issues to which psychiatry can make no well-founded contribution.

PROCEEDINGS OF THE AMERICAN PSYCHIATRIC ASSOCIATION

SUMMARY OF MEETINGS OF COUNCIL AND EXECUTIVE COMMITTEE, MAY 1960 TO MAY 1961

This report presents in summary form the principal actions of the Council and the Executive Committee at meetings held throughout the year. Some routine matters, such as referrals to Committees prior to definitive action, are not included. Copies of the full minutes have been forwarded to the officers of each District Branch and Affiliate Society following the various meetings to keep their members informed of the matters that were considered and the action that resulted.

Executive Committee Meetings, June 23, September 12 and October 27, 1960. Approved the recommendation of the Ad Hoc Committee on Insurance and authorized the transfer of the APA malpractice insurance program from Lloyds of London to domestic carriers effective July 1, 1960. Also authorized the Committee to send a letter to the membership explaining the change of malpractice insurance coverage and to follow this with a brochure on insurance coverage. Heard a report from the Secretary regarding a meeting of a special committee comprised of representatives of the Council, Assembly, Membership Committee and the staff to discuss details involved in certifying District Branches to process APA membership applications. Directed that billing for dues and mailing of publications of the Association will start at the time of the Annual Meeting for new members regardless of when they are elected to APA membership. Directed that the request of a District Branch for certification to process APA membership applications must be submitted to the Secretary by December 15 of a specific year or the request will be held over until after the following Annual Meeting. Considered several items regarding resignations and other membership matters and took appropriate action. Approved the recommendation of Dr. Henry Laughlin, APA representative to the Council on Medi-

cal Television, that the Association retain its membership with this Council for another year and authorized the payment of dues and registration fees from the Council Contingency Fund. Indicated that the APA always welcomes its friends from abroad, particularly during the Annual Meeting, but with full appreciation of the problems involved in planning the Third World Congress of Psychiatry, it was suggested that visits to the U. S. not be encouraged until after the Congress is adjourned. Approved for one year the recommendation of the Board of Tellers to include biographical material on candidates for APA offices, but directed that the plan should be limited to the nominees for the Council and any other office in competition, and the biographical material should be limited to his address, position or employment title, elected offices and Committee Chairmanships that he has held in the activities of the Association. (Amended by the Council, December 2, 1960.) Elected office in District Branches should also be included with the biographical material. The Nominating Committee was directed to gather this information as a part of its work in selecting candidates. Authorized a contribution of \$50 to the National Society for Medical Research from the Council Contingency Fund. Appointed Dr. Reginald Lourie to act as Co-Chairman of the Institute of Child Psychiatry Training to be sponsored jointly by the APA and the American Academy of Child Psychiatry. Appointed Dr. Melitta Schmideberg to represent the Association at the Second United Nations Congress on the Prevention of Crime and Treatment of Offenders which was scheduled to be held in London, August 8-20, 1960. Directed the Treasurer to contact a foundation to solicit a small grant to underwrite the expenses of a visiting lecturer under the auspices of the APA to the Eighth World Congress of the Interna-

tional Society for the Welfare of Cripples. Approved publication of the manuscript on source material dealing with youth and its problems as prepared by the Committee on Academic Education provided sufficient financial support was obtained to offset any losses that would otherwise be incurred by the Association. Was informed of the following Presidential appointments: Drs. Ewald Busse, Maurice Linden and Mathew Ross as Delegates, and Dr. Alvin Goldfarb as Alternate, to the White House Conference on Aging, January 9-12, 1961; Dr. George S. Stevenson as representative at the 1960 annual meeting of the World Federation for Mental Health, August 7-12, in Edinburgh, Scotland; and Dr. Henry Laughlin as representative to the 1960 annual meeting of the Royal Medico-Psychological Association in London. Reaffirmed its previous action (March 1948) favoring inclusion of the name of Miss Dorothea Dix in the Hall of Fame. Agreed to nominate a candidate for the Distinguished Achievement Award presented annually by the medical journal *Modern Medicine*, and unanimously nominated Dr. Earl D. Bond as the APA candidate for this Award. Approved the publication of the brochure "Psychiatric Units in General Hospitals" in accordance with the recommendation of the Committee on Standards and Policies of Hospitals and Clinics. (This brochure was prepared by the Committee in Liaison with the American Hospital Association and its counterpart committee from the AHA.) Directed that the Association would not be able to make a financial contribution to the exhibit proposed by the U. S. Committee for the International Conference on Social Work for display at the Tenth International Conference in Rome in January 1961. Appointed Dr. Anthony Maniscalco as representative to the American Nurses' Association and the National League for Nursing. Heard the Treasurer report that in accordance with a previous directive of the Executive Committee he had contacted the Milbank Foundation and requested a small grant to underwrite the expenses of a guest lecturer for the Eighth World Congress of the International Society for the Welfare of Cripples. A grant of \$1200 was approved by the Foundation with the understanding that

unexpended funds would be returned. Following the payment of the expenses, a small surplus remained in this account. The Treasurer was directed to contact the Foundation for permission to pay a \$250 honorarium to the guest lecturer from the balance. Suggested the appointment of a member of the Committee on Aging from the New York City area as representative to the Second Annual Conference of the National Committee on Aging and authorized payment of expenses not in excess of \$15. Authorized the Treasurer to pay financial obligations of a continuing nature after they have been initially approved by the Council until such time as the obligation may be formally terminated. Authorized the purchase of a new U. S. flag for the Central Office with the expense to be charged against the Council Contingency Fund. Did not approve a proposal from the Board of Tellers that a photograph of each candidate should be included on the ballot along with biographical material. Amended and approved the membership application form endorsed by the Membership Committee. Authorized the Medical Director to negotiate with a travel agency regarding the possibility of chartered flights for APA members and their families to overseas scientific meetings and to ascertain the amount of membership interest in such flights through an announcement in the Mail Pouch. Regarding the proposed tour the U. S. facilities for foreign guests following the Third World Congress of Psychiatry, several guide lines were formulated to assist the APA Liaison Committee with arrangements: (a) The APA would not provide financial help for the travel of foreign visitors who were interested in visiting psychiatric facilities in the U. S. (b) Such travel would be encouraged only after the Congress. (c) An informal tour of one week through the major facilities in the adjacent eastern states of the U. S. would be arranged for the visitors, and in addition, they would be notified that other facilities would be happy to welcome them should their plans involve trips to other parts of the country. The Liaison Committee was specifically encouraged to continue its efforts to arrange a suitable one-week, post-congressional tour of the U. S. facilities and to

explore at its discretion such other hospital-ity measures that seem appropriate. Asked the Secretary to inform the Indian Psychiatric Society that their invitation for the APA to send a representative to their annual meeting in Ranchi, Bihar on February 8-12, 1961 would be taken under advisement.

Council Meeting, December 2-3, 1960.

Amended the previous action of the Executive Committee so that biographical material would be included on the ballot for all nominees for APA office. Amended and approved the recommendations from the Executive Committee regarding ethical complaints as follows: 1. The Secretary shall sign all letters related to ethical charges and the ultimate decisions, favorable or unfavorable, in such matters as an instrument of the Council. 2. When a complaint is received from any source against a member of the APA, the Secretary shall advise the member of the specific complaint and his rights and obligations in dealing with the matter. 3. When the Committee on Ethics recommends that a member be cleared of specific charges and its recommendation is approved by the Council, the Secretary shall write to the accused member stating in unequivocal terms that he is exonerated. 4. When a complaint is received from any source against an individual who is not a member of the APA, the Secretary shall advise the complainant that the Association has no jurisdiction in the matter. Supported the belief of the Long Term Policies Commission that Sections perform a useful function in opening up particular areas of psychiatry and in providing a forum for members to meet, to discuss and to exchange views relating to such areas. Approved the recommendation of the Commission that the five measures regarding Sections adopted by the Council on May 7, 1960 should be studied in operation for at least one year before further changes in the organization and function of Sections are considered. Amended and approved the recommendation of the Commission that reports from Section Chairmen and reports specifically on the operation of the Sections from the Chairman of the Program Committee should be submitted to Council at the time of each Annual Meeting with the understanding that such Sections that do not have

an opportunity to report may present either a written or verbal report to the fall Council Meeting. Amended the recommendation of the Commission and directed that the Committee on Committees assume the function of a Reference Committee and empowered it to use as a consultant the Chairman of any other Committee or Commission necessary to accomplish its purpose. It was agreed that such a Reference Committee should be supplied with the necessary staff assistance. Approved the recommendation of the Commission that from time to time Task Forces should be set up by the Council, when necessary, to deal with problems requiring assistance not ordinarily available to the Committee operating within the area in which the problem has arisen; that such a Task Force should consist of a sub-committee of an existing Committee together with individuals from outside the Association. Membership of the Task Force are to be appointed by the President on recommendation of the Chairman of the Committee concerned. The Task Force should be assigned for a specific area of operation and set up for a limited period of time. Approved in principle the recommendation of the Commission that it would be desirable to have staff assistance made available to each of the three Coordinating Committees and that a fourth staff person should be in charge of staff assistance to all Committee work, but that implementation of the recommendation would be dependent upon the availability of funds. Approved the recommendation of the Commission that when an Archivist-historian is appointed to the Central Office staff, the cross-indexing of Committee reports should be one of his assignments. The recommendation of the Commission that the possibility of listing all papers delivered at meetings organized by the APA which are not published and making the list available to the membership, be referred to the Committee on Internal Management, was disapproved. Approved the recommendation of the Commission that the Program Committee give consideration to the proposal that the Isaac Ray Lecturer have an opportunity to present a lecture on his subject to the members at the Annual Meeting. Reaffirmed its previous action of May 1953 that APA representatives work

with representatives of other national psychiatric organizations looking toward the formation of a world psychiatric organization. Authorized the Executive Assistant to send out the 1961-62 dues notices on or about May 15, 1961 and empowered the Treasurer to borrow sufficient funds to meet current operating expenses of the Association until these dues are received. Approved the budget recommended by the Budget Committee for the 1961-62 fiscal year as presented. Approved a general endorsement of the manuscript "Services for Children with Emotional Disturbances" prepared by the Committee on Child Health of the American Public Health Association. Indicated that since the APA recognizes only the American Board of Psychiatry and Neurology, Inc. as the examining body for certification of specialists, the Association does not evaluate other approving bodies for such certification. Approved the recommendation of the Policy Committee and recommended to the membership the approval of the application of the Prairie Provinces District Branch (Manitoba, Saskatchewan and Alberta) and its assignment to Area Four. Expressed appreciation to Dr. Henry Davidson for the exceptional work he has done as Chairman of the Committee on Constitution and By-Laws. At the request of the Committee concerned changed its name to the Smith Kline and French Foundation Awards Committee. Requested the President to appoint an Ad Hoc Committee to serve in liaison with the Council on Mental Health of the American Medical Association and attempt to extend for a reasonable time the period during which foreign-trained physicians who have not been certified by the ECFMG will be permitted to remain with their hospitals. Authorized the House Committee to offer up to \$37,500 for the property 1807 R Street to complete the parcel of property contiguous to the Central Office. Approved the recommendation of the Committee on Psychiatry of Childhood and Adolescence and established the McGavin Prize to be awarded in the amount of \$500 for the best work in the previous year related to the preventive aspects of the emotional disorders of childhood. This Prize will be on a non-competitive, non-invitational basis and

will not be awarded in any year in which appropriate and important work in the preventive field would not be available or until such time as the Council decides otherwise. It is further understood that income from the bequest will be used for this Award with a portion of the income to be utilized for the expenses of a Selection Committee. Approved the request of the Committee on Mental Deficiency to proceed with the planning of the proposed Exploratory Meeting on Mental Deficiency and authorized the Committee to submit an application for funds in the name of the APA to appropriate sources. Approved the recommendation of the Committee on Public Health regarding the medical provisions of the Immigration and Nationality Act as follows: 1. That the technical medical terms used be those of the international classification. 2. That persons who have had no psychosis within the past 5 years be eligible for admission. 3. That persons with epilepsy who have been symptom-free for one year or longer be admissible. Approved the recommendation of the Committee on Rehabilitation that a liaison representative not be appointed to the Association for Physical and Mental Rehabilitation. Approved the recommendation of the Committee on Rehabilitation that the Council submit a statement on the attitude of the APA on the proposed Congressional Bill HR 12328 on Special Education and Rehabilitation. Indicated that a letter should be prepared for the President's signature expressing the APA's appreciation and congratulations to Miss Mary Switzer, an Honorary Fellow and Director, Office of Vocational Rehabilitation, in recognition of her efforts over the years in rehabilitating the handicapped upon her completion of 10 years of service. Approved the proposal of the Committee on Research to change the emphasis of its Regional Research Conferences, but directed that such Conferences should be continued, and expanded, if possible. Reaffirmed its previous policy regarding non-medical psychotherapists as follows (November 1958): "It is imperative that all psychologists dealing with persons suffering from mental and nervous diseases and disorders should do so only under supervision by psychiatrists and in a medical setting offering adequate safeguards to the patient."

Approved the recommendation of the Committee on Therapy that a physician administering drugs to a patient in collaboration with a non-medical psychotherapist should actively and continuously supervise these treatments to insure the safety of the patient. Approved the recommendation of the Committee concerned and changed its name to the Committee on Psychiatry and Social Work. Approved the request of the Committee on Private Practice for permission to seek funds to investigate the psychosocial dimensions of the use and abuse of outpatient psychiatric health insurance programs. Approved the following Resolution prepared by the Committee on Nomenclature and Statistics and authorized the Committee to speak for the Association in dealing with the American Medical Association regarding this matter: "Resolved That the diagnosis (Page 79, Diagnostic and Statistical Manual of Mental Disorders) 'Chronic Brain Syndrome' without qualifying phrase should be changed in meaning to indicate the presence of a psychosis as is the case in the acute brain syndrome." Agreed that when the APA is invited to send a representative to a foreign meeting, the Association should not be represented unless a member who would be an appropriate representative is visiting the meeting under other arrangements. It was also agreed that ideally the Association would pay the expenses in sending a properly qualified representative to such meetings, but practically, this is impossible because of the expense involved.

Executive Committee Meetings, January 13 and March 4, 1961. Authorized the Treasurer to sell the common stock of General Telephone and Electronics Corporation and Treasury Bonds owned by the APA sufficient to provide a total of \$45,000 which was estimated as the amount of cash necessary to operate the Association until June 1, 1961, when dues for the next fiscal year would be available. Amended and approved the statement on hypnosis prepared by the Committee on Therapy. (Prior to its release, this statement was circulated to the Councillors, who approved it by a mail vote as an official policy statement of the Association.) Authorized continued APA representation to the American Registry of Physical Therapists, and the President an-

nounced the appointment of Dr. George W. Brooks to serve as this representative. Approved in principle a proposed Joint Meeting between the Committee on Disaster and Civil Defense and the National Association of State Mental Health Program Directors with the understanding that the APA could not finance a special meeting for this purpose. It was also understood that if such a meeting were scheduled at the time of the Annual Meeting, the APA would not underwrite the expenses of non-members of APA and that consideration should be given to the possibility of scheduling the Joint Meeting at the time of the Mental Hospital Institute, when the NASMHPD normally meets. Indicated that under ordinary circumstances, Divisional Meetings and Fall Committee Meetings not be scheduled concurrently. Approved any arrangement negotiated by a local committee to handle exhibits for a Divisional Meeting as long as the arrangement is not in conflict with established APA policy. Indicated that except for emergency situations, any matter concerning a Committee should be routed through the responsible Coordinating Committee Chairman prior to consideration by the Executive Committee or the Council. Indicated that there should be no arbitrary objection to dedicating an APA publication to a living member of the Association. Was informed that Dr. Bartholomew Hogan had joined the Central Office staff on March 1 as Assistant Medical Director. Was informed by the President of the appointment of Dr. Alan McLean as representative to a meeting scheduled by the A.M.A. Council on Occupational Health in Chicago on May 6, 1961; also, that Dr. Walter Barton would represent the President at a meeting scheduled by the A.M.A. Committee on Continuing Education of Physicians in March 1961. Directed the Committee on Membership to defer action on all membership applications when the professional competence of the applicant is questioned because of the ECFMG ruling until the matter is clarified by the Council. Instructed the Ad Hoc Committee on ECFMG to explore the possibilities of extending the examination deadline to either January or June 1962 and the establishment of an oral screening examination to select those individuals who

might be able to qualify for a subsequent ECFMG examination after additional training. Indicated that participation in the Exploratory Conference on Mental Deficiency should not be limited to physicians but rather that it should be open to any professional group with the necessary training and interest. Concurred with the President in the appointment of Dr. Mabel Ross as APA representative to the Council of National Organizations for Children and Youth. Approved the establishment of a Task Force on Juvenile Delinquency, requested the President to make the necessary appointments, authorized the solicitation of outside funds for this purpose, and authorized the activation of the Task Force following the submission and approval of a budget. Indicated its desire to continue the relationship with the National Academy of Sciences-National Research Council and was informed by the President of the reappointment of Dr. Henry Brosin as APA representative from July 1, 1961 through June 30, 1964. Approved co-sponsorship of the 1961 Symposium on Mental Health in Business and Industry as recommended by the Chairman of the Coordinating Committee on Community Aspects of Psychiatry. Was informed of the Presidential appointment of Drs. Kenneth Appel and Mathew Ross as APA representatives to the meeting of the American Academy of Political and Social Science in Philadelphia on April 14-15, 1961. Voted not to accept an invitation to become a charter member of the proposed International Association for the Study of Higher Nervous Activity. Agreed that although psychiatry does not have a major interest in this problem from a clinical standpoint, it would be desirable to be represented at the A.M.A. Conference in Chicago on April 13-14, 1961 to develop standard identification devices to assist physicians, police and others confronted with emergencies in which individuals are found unconscious without obvious cause. The President announced the appointment of Dr. Benjamin Boshes to serve as APA representative to this Conference. Reaffirmed its previous decisions regarding a post-Congressional tour of U. S. psychiatric facilities by foreign colleagues following the Third World Congress of Psychiatry and

urged the membership to render all possible hospitality to such guests during their visit.

Council Meetings, May 6, 7, and 11, 1961.

Ratified the President's Statement on Confidentiality as a personal statement and referred the matter to the Reference Committee for the formulation of an official policy statement. Ratified the actions of the Executive Committee *en bloc* since the fall Council Meeting. Approved, as amended, the list of members whose dues are 3 years in arrears and authorized the Executive Committee to reconsider any individual whose unpaid dues are received subsequent to this Annual Meeting. Approved, as amended, the recommendations of the Committee on Membership regarding applications for membership and changes of status in the Association and directed that the list be submitted to the membership for action. Directed the Chairman of the Membership Committee to work with the Speaker of the Assembly and the Central Office, utilizing the services of the Assembly when appropriate, in attempting to reduce the number of members whose dues are in arrears. Raised the membership dues \$5.00 for Associate Members, and \$10.00 for Members and Fellows effective April 1, 1961 in accordance with the recommendation of the Budget Committee. Authorized the Treasurer to deposit the McGavin bequest in a savings account at his discretion. Authorized the Treasurer to expend grant funds from the NIMH for the Conference on Graduate Psychiatric Education and the Conference on Child Psychiatry Training in accordance with the respective budgets and the requests of the Medical Director. Approved the Royal York Hotel in Toronto as the site for the 1962 Annual Meeting on May 6-11. Directed that a letter should be prepared for the President's signature expressing the appreciation of the Council to Mrs. Adolf Meyer for the generous gift of her late husband's library to the Association. Approved the recommendation of the Medical Director to utilize the Coordinating Committees to analyze the final report of the Joint Commission on Mental Illness and Health, to assist in the formulation of an official position on the Joint Commission's recommendations, and to prepare for active participation in their implementation.

Amended the draft of the proposed new Constitution and By-Laws but deferred further action on the document until the 1961 Fall Council Meeting to give the Assembly and other appropriate bodies in the Association ample opportunity to study it. Approved the recommendation of the House Committee and authorized up to \$800 from available funds to prepare and frame pictures and quotations of Past-Presidents from APA's first century. Authorized the House Committee to continue to express interest in the property immediately north of the Central Office on 18th Street. Authorized the House Committee to purchase property 1807 R Street at its discretion for a price that the Committee considers satisfactory. (The 1807 R street property adjoins the Central Office and is the only one of three contiguous row houses not presently owned by the APA.) Approved the recommendation of the Ad Hoc Committee on Internal Management and reconstituted it as the Internal Management Commission with the following membership: Dr. Robert Felix, Chairman; Dr. Jack R. Ewalt; Dr. Addison Duval; Dr. C. H. Hardin Branch; and Dr. Mathew Ross; and as *ex-officio* members, the President and the Chairman of the Budget Committee. Expenses for the Commission will be charged against the Council Contingency Fund. Approved the following 7 recommendations prepared by the Commission on Long Term Policies after the Commission reviewed recommendations prepared by the Standby Committee on *The American Journal of Psychiatry*: 1. That editorial policies should be more closely correlated with the overall policies of the Association. 2. That the operation of the Journal should be reviewed by Council, or by a Council-designated body, at regular intervals, preferably every 6 years. 3. That the Editor-in-Chief should be a Fellow of the Association; that he should be appointed for a 6-year period with a reasonable anticipation of reappointment until a predetermined retirement age. 4. That the Editorial Board should be a working Board, holding regular meetings. 5. That the members of the Editorial Board should be appointed by Council on nomination by the Editor-in-Chief after consultation with the Editorial Board. 6. That the term of office

for members of the Editorial Board should be 6 years; 2 members of the Board to reach the end of their tenure of office each year with the possibility of reappointment. 7. That the major publication activities of the Association should be integrated with respect to their business aspects. Reaffirmed its desire to see the establishment of a world psychiatric organization, recommended that this be done by reconstituting the existing body, and suggested that such action be taken at once. Discharged the Committee on Increasing Responsibilities with thanks at the Committee's request. Approved the recommendation of the Committee on Committees that the duration of the Fall Committee Meetings should be determined on the basis of yearly workloads of the various Committees and that the Committee on Committees be charged to report to the Council at the Annual Meeting its recommendations as to the time needed for the forthcoming Fall Committee Meetings. Approved the recommendation of the Ad Hoc Committee on District Branch Committees that each Coordinating Committee Chairman be instructed to request that each of his Committees designate one of its members as District Branch Liaison Committeeman. Recorded a vote of appreciation to the Program Committee in recognition of its work upon receiving the Committee's report. Approved the following Resolution: "The Council recommends to the membership that the American Psychiatric Association in its Annual Meeting 1961 express its concern over the exclusion of mental patients (along with tubercular patients), under certain conditions, from benefits of Federal Public Assistance in several categories and as amended in the Total Disability Law and the Kerr-Mills Bill (Public Law 87-778). It is believed that due to changed conditions and the recent provision of Federal funds for treatment of other medical conditions, mental patients are placed in an inequitable position and prevented from obtaining treatment equal to that afforded persons with other diseases. "It is requested that leaders of the administration and the Congress arrange for a study in this matter and all the implications of treatment and cost as recommended by the President's Advisory Committee on

Public Assistance, January 1960, so that the laws may be changed if justification is found." Authorized Dr. D. Ewen Cameron to explore the possibility of encouraging the Modern Founders to assist in the development of the APA Endowment Fund with the APA Treasurer continuing to act as recipient of such funds as may become available. Elected Dr. Walter E. Barton as Moderator for the next year. Elected Dr. Robert H. Felix and Dr. M. Ralph Kaufman to serve on the Executive Committee. Approved the appointment of Dr. Jack A. Wolford and Dr. Gene L. Usdin to serve on the Membership Committee until 1964. Approved the recommendations of the Incoming President and continued the following Ad Hoc Committees for the next year: Convocation, District Branch Committees, Insurance, Joint Committee with the Canadian Psychiatric Association, Pre-Registration at the Annual Meeting, Recognition for Allied Service Personnel in Mental Hospitals (the name of this Ad Hoc Committee was later changed to Recognition for Psychiatric Service Personnel, at the request of the Committee). Approved the scheduling of a Divisional Meeting in St. Louis on November 7-9, 1963. Approved a letter to the Attorney General of the U. S. prepared by the Committee on Psychiatry and the Law and authorized the Committee to send the letter over the President's signature. (This letter commended Mr. Robert Kennedy for recognizing that delinquency is a problem solvable by scientific means; called his attention to the availability of specialists within the APA who have compiled considerable knowledge about effective ways of handling delinquents, and offered to cooperate with him in any way he might suggest in dealing with this social illness.) Approved the following requests from the Ad Hoc Committee on Recognition for Psychiatric Service Personnel: 1. Authorization to obtain estimates of costs involved and the number of participating subscriptions that could be

sold to an expanded APA Mental Hospital Services program to include a news sheet or supplement prepared specifically for psychiatric service personnel. 2. Authorization to investigate sources of financial support for at least a 2-year trial in providing the proposed services. 3. Authorization to study sources of revenue which would allow the APA to provide the several forms of recognition proposed for psychiatric service personnel without added expense to the Association. (The Committee suggested recognition pins and wallet or purse identification cards.) Appointed Dr. Lorne D. Proctor to the Editorial Board to fill the vacancy created by the resignation of Dr. John Whitehorn. Authorized \$150.00 honoraria to Dr. Heinz Von Foerster and Dr. Hubert W. Frings in addition to the reimbursement of their expenses, in recognition of their outstanding papers on communication presented at the 1961 Annual Meeting. Nominated Dr. Ewald W. Busse for a 4-year term on the American Board of Psychiatry and Neurology as one of the representatives of the APA. Approved in principle the establishment of a central repository for the collection, analysis and dissemination of mental health manpower information to be administered by the National Institute of Mental Health and offered the cooperation of the APA in the development and implementation of this endeavor. Approved the recommendation of the Ad Hoc Committee on Insurance and authorized a revision of the life insurance units available to the membership under the APA insurance program to \$25,000 per unit and authorized the Treasurer to send an appropriate announcement to the membership. Requested the Membership Committee to present its recommendations regarding candidates for advancement to Fellowship at the 1961 fall meeting of the Council, if possible.

C. H. Hardin Branch, M.D.,

Secretary, 1960-61.

REPORT OF THE TREASURER

I am happy to present to you my second annual report as Treasurer.

In general, our financial stability has continued to be good during the past year. Those problems which have developed have concerned principally the final adjustment in cash reserves which were depleted because of the purchase several years ago of our Central Office Headquarters Building and its rehabilitation; secondly, the purchase during the year of two adjacent properties at 1809 and 1811 R Street N.W., Washington, D. C.; and thirdly, the need to expand our various committee activities.

These needs have been carefully considered and Council has decided to recommend to the membership a raise in dues which will produce the necessary funds to meet the requirements just mentioned. It was necessary to delay the submission of dues notices from February to May 15th in this connection. The dues problem will be presented to you on Wednesday.

As of March 31, 1961, our assets amounted to \$601,114, not including special purpose and restricted funds of approximately \$73,922. Our fixed assets in Washington amount to a value of \$331,737, excluding an accumulated depreciation reduction of \$23,619. Beginning in 1959-60, buildings are being depreciated at the rate of 2% per

year and furniture and equipment at the rate of 33 1/3% per year.

We hold marketable securities with a present value of \$145,000, which cost us \$82,000.

Our income for the year amounted to \$622,666, while our expenses were \$573,000. Special mention should be made of the profitable operations of the News Letter and Mail Pouch, the Mental Hospital Service and Institute of the *Journal*. The various committees also are to be commended for staying within budget allocations.

The Treasurer is happy to report that our recommendation of last year for the appointment of an Internal Management Committee has been implemented during the year and on yesterday the Council changed this Committee to a Commission for more stable operation.

In conclusion, the Treasurer would like to assure the membership that the funds of the Association are received and disbursed under proper operating procedures and are safeguarded at all times.

My special thanks are extended to Mr. Austin Davies for his cheerful cooperation and helpful assistance throughout the year.

Addison M. Duval, M.D.,

Treasurer.

REPORT OF COORDINATING COMMITTEE CHAIRMAN ON THE TECHNICAL ASPECTS OF PSYCHIATRY

I have the pleasure of reporting on the wide ranging activities of your Committees on the Technical Aspects of Psychiatry. In a composite presentation such as this, it is difficult to adequately reflect the scope of the work accomplished and impossible to suitably note the contributions of the various committee members. Nevertheless, in enumerating the highlights of the year's work, the Association will again recognize its indebtedness to the individual members of the various committees.

The members of the Committee on Aging,

under the chairmanship of Ewald W. Busse, and other members of the American Psychiatric Association, participated in the White House Conference on Aging as well as in the preliminary state meetings. The effective work of psychiatrists was reflected in a number of important reports emanating from the White House Conference. A comprehensive review of the accomplishments of the Conference will be given at this annual meeting. Psychiatrists' interest and training in the field of Geriatrics was resurveyed in 1960. The data have been

analyzed and a report of the results prepared by Dr. Goldfarb for submission to Council.

The Committee on the Psychiatry of Childhood and Adolescence, chaired by Reginald S. Lourie, has secured funds to conduct a Conference on Training in Child Psychiatry in conjunction with the American Academy of Child Psychiatry. Dr. Lourie and Dr. Othilda Krug, the co-director of the Conference for the Academy, have set up planning meetings for a preparatory commission to begin functioning. Mr. Robinson of the Central Office is an integral part of the planning phases.

A committee proposal for the establishment of a task force to consider the role of the psychiatrist and the APA in juvenile delinquency has been approved by Council. Dr. Stuart Finch has accepted the chairmanship of this task force and is making plans for its membership and meetings. There is a good possibility that foundation support will be available for the work of this task force.

The APA received a bequest from the late Dr. Agnes P. McGavin to be used in the field of child psychiatry. On recommendation of this committee, Council approved a McGavin prize to be awarded on a non-competitive, non-invitational basis for the best work in a previous year related to the preventive aspects of the emotional disorders of childhood. A selection committee is being appointed for this purpose. On recommendation of this committee, Council approved an APA official representative, Dr. Mabel Ross, to the Council of National Organizations for Children and Youth which is intended to implement the recommendations of the 1960 White House Conference on Children and Youth and plan for the 1970 meeting.

J. Sanbourne Bockoven, chairman of the Committee on the History of Psychiatry, indicates that the committee has developed a 3-fold definition of its function: 1. The procurement of accurate record keeping of the actions, decisions and policymaking of the Association; 2. The encouragement of study and evaluation of the existing body of recorded information as it reflects the successes and failures of psychiatric endeavors

of the past; 3. The encouragement of awareness among Association members of our continuous need for application of historical insights in charting future courses of professional and organizational activity.

A symposium is in preparation on "The Historical Role of the Physician in Relation to the Mentally Ill" to be submitted for the annual meeting in 1962. Also, plans are being laid for an exhibit at the 1962 annual meeting commemorating the 150th anniversary of the publication of Benjamin Rush's *Medical Inquiries and Observations upon the Diseases of the Mind*, published in Philadelphia in 1812.

Members of the committee have visited Central Office and the New York Office to identify materials of possible archives importance. Contact has been made with senior members of the Association in an effort to secure first-hand accounts of the modern history of psychiatry. Efforts have been made to locate portraits of historical importance to psychiatry and the possibility of developing a history section of the library in the Modern Founders room in the Central Office has been explored. This committee has contacted the district branches of the Association in an endeavor to survey APA membership interested in participating in a project to prepare a series of publications on the history of psychiatry.

The Committee on Medical Education, C. Knight Aldrich, chairman, reviewed its role in the forthcoming conference on graduate education; reviewed and made recommendations concerning overall committee structure; participated with the Committee on Therapy in deliberations relative to the policy statement on "hypnosis"; and sponsored a round table at this annual meeting on "A Matching Plan for Resident Selections in Psychiatry."

The Committee on Mental Deficiency, under the Chairmanship of George Tarjan, requested and received Council approval for an exploratory meeting on mental deficiency and has been authorized to apply for outside funds. It was further recommended that the securing of such support should not modify the intent of the association to develop the conference under the primary auspices of the APA.

Under authority of Council, the president of the Association has written to the president of the American Association of Mental Deficiency regarding a liaison relationship between the APA and the AAMD.

This committee has reaffirmed its support of the principle of unity, that all mental health programs be under a single administrative agency, and is, therefore, in opposition to any trend which would separate programs for the mentally retarded from the organizational unit having responsibility for the care and treatment of the mentally ill.

This committee recommended the inclusion of mental retardation units in the proposed *study of standards for public mental hospitals* under the auspices of the Committee on Standards and Policies of Hospitals and Clinics. The latter committee has indicated its recognition of the need to include such institutions in its proposed project.

An item given high priority in future activities is the development of a suggested basic curriculum in mental retardation for residents in psychiatry.

James V. Lowry, chairman of the Committee on Public Health, reports that the committee's project relative to the care given psychiatric patients in nursing homes, including the licensing and supervision provided, will be completed within the next year. This is being done through the cooperation of district branches and state societies. The committee indicates that information at hand supports the need for district branches to interest themselves in local licensing law provisions for psychiatric patients in nursing homes.

During the year, the committee has assisted the American Public Health Association in reviewing a *citizen's guide to a community mental health survey* and also, in conjunction with the same association, studied and made recommendations relative to a publication entitled: *A Guide to Control Methods for Mental Disorders*. The Committee on Public Health sees this type of assistance to the American Public Health Association as one of its principal functions and one which will extend the influence of the APA to the members of another large and nationally important pro-

fessional group.

The Committee on Public Health reviewed the present medical provisions of the Immigration and Nationality Act and recommended, which was subsequently approved by Council, that the act be changed to allow individuals to become eligible for admission to this country who have been without psychosis within the preceding 5 years, and persons with epilepsy who have been symptom-free for one year or longer.

It was also recommended that the technical medical terminology used in the Act correspond to the international classification.

Benjamin Simon, Chairman of the Committee on Rehabilitation, represented the APA at various national and international meetings and also on committees of various national organizations in the general field of rehabilitation. Dr. Simon also served as consultant for several state mental health surveys by the Association.

In conjunction with the Committee on Therapy, a joint subcommittee was formed to study and evaluate occupational therapy as a treatment procedure.

The committee indicated its opposition to any legislation which would create a separate office of special education and rehabilitation on a federal level. This position was approved by Council as a policy of the Association.

A round table meeting on "Integration of the Services of Administratively Independent Psychiatric Rehabilitation Agencies" was sponsored by this committee for the current annual meeting.

A pilot study on rehabilitation, for which the committee received a grant a number of years ago and which has been under way at the Boston State Hospital, is being completed and a publication on this work is anticipated during the ensuing year.

Under the chairmanship of Milton Greenblatt, the Committee on Research reports the following:

The committee, through its representative Dr. Ulett, assisted at the October 1960 regional research conference on "Psychiatric Research in Public Service," sponsored by the Mayo Clinic and the St. Paul Department of Public Welfare. The manuscript of

this conference is now being prepared for publication in the *Psychiatric Research Reports* series.

One of the main concerns of the committee during this period was the obtaining of funds necessary to publish future issues of *Psychiatric Research Reports*. Various sources are now being contacted in this regard.

The *Proceedings of the Iowa City Regional Research Conference* were published in November 1960 as the 13th in the "Reports" series and is entitled "Child Development and Child Psychiatry—In Tribute to Dr. Arnold Gesell in his 80th Year."

For the December 1960 meeting with the American Association for the Advancement of Science, a well-received symposium on "Emotions in Man" was organized by committee representative Dr. Knapp.

The Adolf Meyer memorial lecture at the present annual meeting will be given by Dr. John Bowlby of Tavistock Clinic, London, who will speak on "Childhood Mourning and its Implications for Psychiatry." The pharmaceutical company, which has been the sponsor of the 5 lectures in this series, will continue its support for one more year and may possibly consider further sponsorship.

Also, at this annual meeting, the Committee on Research will present a round table panel. Dr. Epstein has organized and will moderate a discussion on "The Mental Hospital in Transition: Research Setting and Research Potential."

The Committee on Therapy, Henriette Klein, chairman, during the current year, developed a statement on hypnosis after consultation with various committees, including the APA Committee on Medical Ed-

ucation, Committee on Research, Committee in Liaison with the American Academy of General Practice, as well as the Council on Mental Health of the American Medical Association. This was submitted to Council and approved with circularization to the entire membership.

As previously reported by the Committee on Rehabilitation, a subcommittee on occupational therapy was appointed in conjunction with the Rehabilitation Committee to conduct an inquiry into current practices and research in that particular field. This study is nearing completion.

The Committee developed a policy on the administration of certain potent drugs used by non-medical psychotherapists, which was approved by Council.

The committee members were consultants for Dr. Paul Feldman on his study of the Current Status of Psychotherapy with Hospitalized Schizophrenic Patients which includes the extent to which psychotherapy is currently in use for that group of patients, and the individually determined judgment of its effectiveness by each hospital-facility in the sample studied. This will be published by him as an independent study.

All committees considered the suggestions made by the president to strengthen the APA committee structure and also reviewed the functions of their individual committees. Their recommendations have been submitted to Council.

In concluding this report, I wish to thank the various committees for the cooperation and support given me and to express my appreciation for the opportunity of working with them during these several years.

Harvey J. Tompkins, M.D.,
Chairman.

REPORT OF THE COORDINATING COMMITTEE CHAIRMAN ON COMMUNITY ASPECTS OF PSYCHIATRY

It is again an honor to represent through this report the 10 Committees of the Community Aspects of Psychiatry. As noted in the Presidential Address, shifts in hospital practices are making and will make even more in the future, psychiatric consultation, diagnosis and treatment tasks at the com-

munity level larger and more challenging. The community aspects of psychiatry certainly penetrate more widely in our Association's activities than is represented by these 10 committees. Nevertheless, these do have the heavy responsibility of furnishing ideational leadership to the Association in

this broad field. As coordinator, I am grateful to the chairmen of the committees for their leadership in services to you, the members of the Association. It was a pleasure to note that 3 of the 4 publications mentioned in Dr. Ross's report were the work of committees in this group. They were the glossary, produced by the Committee on Public Information, the annotated bibliography, *Sources of Information Behavioral Problems of Adolescence*, a product of the Committee on Academic Education, and the pamphlet on *Mental Health on the Job*, by the Committee on Occupational Psychiatry. The latter document, now out about 1 year, has sold 24,000 copies. Sales of the glossary are astronomical; they were brought to your attention last year in this report.

The Committee on Academic Education, from the Chairmanship of which Dr. Douglas Darling is retiring after very productive years, is studying the feasibility of a residency training program for psychiatrists in the mental health of college students. Its round table for this meeting, on Value Systems in Higher Education, has been carefully planned around an excellent discussion group. As one of the guardians of the money of our Association, this must be noted as having been accomplished at no expense to the Association. The Committee planned, and a member carried out, a study on the influence of the history of prior psychiatric treatment on college acceptance of a student for admission.

The Committee on Disaster and Civil Defense and on National Defense, Drs. Ed Koller and John Caldwell, Chairmen, respectively, have for the most part, integrated their work this year. They are literally facing life and death problems; and I sympathize with them as they wrestle mightily with what we will be responsible for in time of disaster. Their Sunday night discussion brought a conclusion that at least during the period of first impact, our job is likely to be that of a physician more than that of a specialist; perhaps this realization might have partaken in the motivation for President Felix' pleas in his address. While struggling still with the basic problem of the role of the psychiatrist in disaster, these groups are collaborating

in investigative and educational conferences. The collaboration of the Armed Services and the Office of Defense Mobilization with these committees deserves the thanks of the Association. The committee has sought and attained collaboration in the District Branches of the Association.

The Committee on International Relations, led by Dr. Lothar Kalinowski, entertained our foreign guests at luncheon. This group has studied and recommends the proposal to form a World Psychiatric Association. It has helped arrange opportunities for colleagues from abroad to reach psychiatric centers in this country, and is willing, with the help of Central Office staff, to aid our membership with recommendations for places of scientific interest to visit when abroad. As might be expected, this Committee is interested in the field of transcultural psychiatry and its development as a scientific field.

The Committee on Leisure Time and Its Uses, Alexander Martin, retiring Chairman, has cooperated with the Outdoor Recreation Resources Review Commission in arranging a 3-day conference on the topic, "Leisure, Recreation and Mental Health" to take place in early June. This multidisciplinary conference will undoubtedly result in clarification of aims and broader recognition of opportunities in this area of growing importance. The "package" of information on psychiatry and leisure collected by this Committee is in considerable demand. This group also publishes a newsletter so that our membership may have the latest information and be stimulated to interest in this field. A survey of teaching centers regarding the place of the subject of leisure time usage in teaching has been completed, as is a bibliography in this field.

The Public Information Committee, Henry Laughlin, Chairman, has its regular tasks of maintaining the Association's relations with the press at our annual meeting, a task done so well over the years that our policies have become models for other national professional organizations. Throughout the year, the committee gives consultation to writers and other producers of material which may have an effect on the public image of psychiatry. The Summary

of Scientific Papers, available for this Meeting, represent part of the work of this committee.

The Committee on Occupational Psychiatry, Ralph Collins, Chairman, has continued its multiple educational activities. Its contacts extend broadly, touching many other professional organizations, including the A.M.A. and government agencies interested in the general problem of rehabilitation. As already noted, the pamphlet on *Mental Health on the Job* has proved extraordinarily successful. This group publishes a quarterly newsletter distributed to about 500 persons particularly interested in mental health in industry.

Preventive Psychiatry, Dr. Henry Work, Chairman, is working on a series of papers, one of which is complete, for the education of general practitioners in certain aspects of psychiatry. Their enthusiasm is attested by the fact that they will need an extra meeting next year. The Committee has collaborated in state surveys. It is looking ahead at its next task, even while involved in the present one.

Dr. Earl Loomis' Committee on Religion and Psychiatry has done a study of our membership's attitudes in the fields represented. This committee is exploring the

area of its interests in its discussions.

The Committee on Veterans, under Dr. Seymour Rosenberg has studied the problems of the residency training programs of Veterans Hospitals, recommending strongly the further development of relationships with medical schools. This group is originating a further study of this feature of residency programs. The extension of Veterans' psychiatric programs to include newer techniques such as half-way houses, home care and paid work programs are recommended for further extension. This group is again studying the problem of recruitment facing the Veterans Administration to find ways of being helpful in this persistent issue.

Each committee has re-examined its terms of reference. The resulting statements will now be edited and codified in a manual so that continuous work can be assured. Each committee will make a special study of the Joint Commission Report as to pertinence of material for the Committees' fields of work. The addition of Dr. Hogan to the staff should further enhance the usefulness of committee work by affording more efficient administrative help and guidance.

Paul V. Lemkau, M.D.,

Chairman.

REPORT OF THE COORDINATING CHAIRMAN OF THE COMMITTEES ON PROFESSIONAL STANDARDS

I have the honor of presenting a summary of the activities of your 10 Standing Committees on Professional Standards. This completes my first year of responsibility as Coordinating Chairman and I am very pleased to commend the diligence of each of these Committees whose year-long efforts in your behalf have not only enhanced the stature of our Association in its many activities but also contributed significantly to the improved welfare of those whose care is our charge. Of necessity the work of these Committees in its major essentials is long term. The scope of the problems to which they address themselves preclude easy, rapid solution. In full appreciation of this

the Committees voluntarily have devoted much time and effort and have earned our thanks. I personally am grateful to their Chairmen and each individual member for their help and cooperation.

The Committee on Liaison with the Academy of General Practice has expressed a continuing interest in document "Psychiatry for the Non-Psychiatric Physician: a Bibliography" published by the National Library of Medicine. Currently, this publication is being revised and the Committee has recommended the addition of psychiatric annotations for each bibliographic listing.

As you know, the work of this Committee has been greatly facilitated by its participation in the General Practitioner Education Project in which our Association joins the American Academy of General Practice. In this connection, it plans to document the work done thus far as well as plan for new projects which will extend its liaison function to other national organized medical groups.

The Committee plans active participation in a conference planned for teachers of postgraduate psychiatry courses for non-psychiatric physicians which is tentatively to be held in Washington this fall. It also co-sponsors a regional AAGP-APA Conference to further postgraduate psychiatric education. In this connection one of its continuing concerns, the limitations and boundaries in psychiatric treatment by non-psychiatrist physicians, will be furthered by these activities.

The Committee in Liaison with the American Hospital Association has expended much effort successfully in the area of intergroup relations. A major undertaking which shortly will have the collaborative approval of the American Hospital Association is an important brochure on "Psychiatric Services in General Hospitals." This has had a final editing and we can anticipate its early release.

This Committee has a wide range of interests which, by their nature, overlap the concerns of other Committees and therefore the Association profits the more. In this frame of reference there is the Blue Cross plan for insurance for psychiatric patients, the American Bar Foundation project on the statutory provisions which safeguard the rights of the mentally ill, the problem of the legal implications involved in the responsibility for patients upon leaving the hospital as well as developments in related educational areas.

The Committee on Mental Hospitals functions in 6 areas: 1. The improved application of psychiatric standards used by the Joint Commission in Hospital Accreditation; 2. Cooperation with the enterprises of the Mental Health Service; 3. Efforts to

extend the scope of coverage in prepaid medical care programs to include mental illness; 4. Collation of material relating to the development and operations of mental hospitals; 5. Sponsorship of our annual round tables; 6. Collaboration with the APA Program Committee. Latterly the Committee has had a keen interest shared with others in the effects of the ECFMG on the staffing patterns in mental hospital facilities. It has also a collaborative interest in the work of an Ad Hoc Committee concerned with Allied Psychiatric Service Personnel.

The Committee on Psychiatric Nursing enjoys a mutually profitable relationship with national nursing organizations with whom it shares responsibility for the planning of a conference which will consider the nature of psychiatric nursing and the changing role of the nurse. It has jointly sponsored with the National League for Nursing a Seminar Project for Teachers of Psychiatric Aides. It proposes to explore the advisability of convening a multidisciplinary conference to be concerned with the nursing needs of the mentally ill. In this connection the Committee is involved in liaison efforts related to the accreditation of schools of nursing.

Committee on Nomenclature and Statistics is involved in the periodic revision of the Diagnostic and Statistical Manual of the APA. In this role it has recently been concerned with the ramified problem of making the APA classification interchangeable with the International one. The magnitude of this problem can be appreciated immediately if you will consider how deeply we and our hospitals are embedded in the existing system of maintaining hospital records. The Committee seeks a series of minimal changes which will leave much untouched, yet, by a judicious dropping out of certain categories and slight alterations of others it is hoped that the final product will be not only translatable but also more accurately reflective of current opinion and practice.

The work of the Committee on Psychiatry and the Law too is basically a long term operation. Such fundamental questions as

those involving privileged communication, the rights of the mentally ill, confidentiality, problems related to delinquency, the thorny issues of criminal responsibility and the like are not encompassed by any quick, extempore effort.

We are fortunate in the composition of the Committee to have a panel of distinguished authorities whose expertise covers the gamut of this important area in which psychiatrists, perhaps more than any other discipline in medicine, are intimately involved.

The delicate but vital area of professional standards, practices and relationships to which the Committee on Relations with Psychology devotes its attention needs little comment. The membership of this Association is familiar with these problems, the activities and efforts of its predecessor Committees and the policy positions taken by this Association in the recent and more distant past.

In its currently constituted form the Committee is doing yeoman work in an effort to arrive at mutually agreed and acceptable positions which will better define our relations with the national association which represents our colleagues in psychology.

These areas of overlap among related professional disciplines require careful delineation and definition and the Committee is to be commended for its diligence, broad vision and tact.

The Committee on Psychiatry and Social Work (you will note a change in the name of this Committee), feels, with Council, that this change recognizes more accurately the developments which have taken place in social work itself as well as defines more precisely the increasing scope of the Committee's concern. In testament of this, the Committee has established a series of liaisons with the Council on Social Work Education, the American Sociological Association, the American Probation and Parole Officers Association as well as maintained the established relationships it has enjoyed with the national associations representative of psychiatric social service workers.

Here too, the problems of defined roles and responsibilities, the scope of individual and collaborative undertakings and their many derivative aspects require the expenditure of much time and effort for which the Committee deserves our sincere thanks.

The Report of the Joint Commission encompassing its recommendations only serves to highlight the task of the Committee on Standards and Policies of Hospitals and Clinics concerned as it is with studies leading to a reformulation of acceptable standards and patterns of staffing and operation in treatment facilities for the mentally ill and the mentally retarded. Necessarily this work requires both extensive and continuing study to develop a qualitative evaluation of service rather than a qualitative measurement of operations which up to now has been the gauge for judgment.

This undertaking is also collaborative in its scope as are many of the related functions of the Committee and therefore extensive liaison activities are among its other duties. The range of responsibility for a definition of hospital bed ratio on the one hand to the care and disposition of records on the other give some idea of the ramifications of this Committee's deliberations.

The burgeoning of private psychiatric practice in recent years is reflected in the composition and agenda of the Committee on Private Practice. Office practice, that conducted in private hospitals as well as practice in general hospitals are areas within its purview.

The troublesome area of health insurance provisions for psychiatric care of all grades and levels has been a pressing concern of this Committee. To this end they have undertaken a series of studies with knowledgeable persons and representatives of other groups, agencies and corporations involved similarly. They serve as consultants and as a reference committee for the resolution of many of the trying issues which grow out of the use and abuse of psychiatric health insurance programs.

Howard P. Rome, M.D.,
Chairman.

NEWS AND NOTES

WORLD PSYCHIATRIC ASSOCIATION.—The first World Congress of Psychiatry was held in Paris in 1950, the second in Zurich in 1957, and the third in Montreal in 1961. In between meetings an international body for the organization of world congresses of psychiatry was charged with planning the assemblage. At the last meeting in Montreal, Canada, it was decided to change this organization to the World Psychiatric Association. This was agreed to unanimously by the 40 representatives of the various countries. The international committee, elected by the General Assembly, is made up of :

H. Barahona Fernandes (Portugal) ; D. Blain (U. S. A.) ; M. Bleuler (Switzerland) ; F. J. Braceland (U.S.A.) ; H. Burger-Prinz (Germany) ; J. A. Bustamente O'Leary (Cuba) ; D. E. Cameron (Canada) ; J. Delay (France) ; H. Delgado (Peru) ; H. Ey (France) ; R. H. Felix (U. S. A.) ; M. Gozzano (Italy) ; S. Hayashi (Japan) ; H. Hoff (Austria) ; A. Jus (Poland) ; G. Langfeldt (Norway) ; J. J. Lopez Ibor (Spain) ; W. Overholser (U. S. A.) ; A. C. Pacheco Silva (Brazil) ; J. G. Prick (Holland) ; W. Sargant (Great Britain) ; C. A. Seguin (Peru) ; P. Sivadon (France) ; E. Stromgreen (Denmark) ; and J. Zutt (Germany).

The officers of the World Psychiatric Association are :

President : D. E. Cameron (Canada)
Vice-President : F. J. Braceland (U. S. A.)
General Secretary : H. Ey (France)
Assistant Secretaries : W. Sargant (Great Britain) and J. J. Lopez Ibor (Spain)
Treasurer : P. Sivadon (France)

A special meeting of the General Assembly will be held in 1962 in Geneva in order to transact the business of this organization and plan the next World Congress. The offices of the World Psychiatric Association will be located in Geneva, Switzerland.

AMERICAN ELECTROENCEPHALOGRAPHIC SOCIETY.—The newly elected officers of the American Electroencephalographic Society, elected at the June 1961 meeting in Atlantic

City : Charles E. Henry, Hartford Connecticut, President ; Cosimo Ajmone-Marsan, Bethesda, Maryland, President-Elect ; Kenneth A. Kooi, Ann Arbor, Michigan, Secretary ; Isadore S. Zfass, Richmond, Virginia, Treasurer.

HENRY POLLAK MEMORIAL LECTURES.—Monroe Eisner, president of Monmouth Medical Center, Long Branch, N. J. has announced the inauguration of the Henry Pollak Memorial Lectures which this year will bring to this country Dr. Lipot Szondi of Zurich, founder of the International Congress for the Study of Schicksal Psychologie (analysis of destiny).

The lecture series is underwritten by Maurice Pollak of West Long Branch, N. J., in memory of his father, the late Henry Pollak. The Pollak Foundation is also the source of funds which established and helps to maintain the Pollak Clinic, the community mental hygiene service of the Monmouth Medical Center of which Milton E. Kirkpatrick, M.D., is director. Present plans call for Dr. Szondi to spend the week of November 3 in the United States during which time he will present 3 all-day seminars at the Pollak Clinic, 1 lecture at Princeton University and 1 lecture in New York City.

RESEARCH TRAINING IN PSYCHIATRY.—A 2-year program of research training in psychiatry leading to the degree of Doctor of Medical Science is available at the State University of New York Downstate Medical Center. It is open to M.D.s who have completed 3 years residency training. Candidates who have completed 2 years will also be accepted : the final year of residency to be taken at the psychiatric division of Kings County Hospital concurrently with the research course. A broad interdisciplinary faculty will conduct the courses and supervise the work of candidates. Extensive clinical and laboratory facilities are available.

Each candidate accepted will be granted

a fellowship of \$6,000 for the first post-residency year and \$7,000 for the second. These fellowships may be supplemented by stipends in special cases. Three-year candidates will receive \$7,100 for the final residency year.

Applications for the academic year beginning September, 1962 should be submitted before February 1, 1962. For information write to: Office of Admissions, Downstate Medical Center, 450 Clarkson Avenue, Brooklyn 3, New York.

DR. DANIELS HONORED.—On May 19, 1961, The Association for Psychoanalytic Medicine in conjunction with the Columbia University Psychoanalytic Clinic and its Alumni Association tendered a dinner in honor of Dr. George E. Daniels, Retiring Director of the Columbia University Psychoanalytic Clinic. Among the distinguished guests paying tribute to Dr. Daniels were: Dr. H. Houston Merritt, Dean of the Columbia University College of Physicians and Surgeons; Dr. Carl Binger; Dr. Nolan D. C. Lewis; Dr. Sandor Rado.

The Psychoanalytic Clinic's new Director is Dr. George S. Goldman.

AMERICAN ASSOCIATION OF NEUROPATHOLOGISTS.—At the 36th annual meeting of the American Association of Neuropathologists, the following members were elected to serve as officers for the current year: David Cowen, M.D., New York, N. Y., President; Leon Roizin, M.D., New York, N. Y., President-elect; Angel Pentschew, M.D., Baltimore, Maryland, Vice-President; Irwin Feigin, M.D., New York, N. Y., Secretary-Treasurer; Humberto Cravioto, M.D., Mexico D.F., Mexico, Assistant Secretary-Treasurer.

DR. APPEL HONORED.—The Department of Psychiatry of the University of Pennsylvania honored Dr. Kenneth E. Appel, chairman of the department and professor of psychiatry, at a reception, June 23, at the Overbrook Golf Club, Bryn Mawr, Pa.

Dr. Appel, past president of the Ameri-

can Psychiatric Association has completed his 31st year on the School of Medicine faculty. The new laboratory for research in psychiatry was dedicated to Dr. Appel in September 1960.

He is president of the national Joint Commission on Mental Illness and Health, established by Congress in 1955 and financed with a grant of \$1.5 million from the National Institute of Mental Health to survey the nation's resources for combatting mental illness. The 11th and final volume of the Commission's report was published this spring.

THE DAVID COLE WILSON LECTURE.—The 3rd David Wilson lecture at the University of Virginia was given at Charlottesville, April 21, 1961 by Dr. William B. Terhune, Medical Director, the Silver Hill Foundation, New Canaan, Connecticut. The subject of Dr. Terhune's lecture was The Treatment of the Phobic Patient.

The lecture proper was preceded by a delightful and fully merited tribute to Dr. Wilson.

THE SOCIETY FOR THE SCIENTIFIC STUDY OF SEX.—The 4th annual meeting of the Society will be held at 9:30 a.m., November 4, 1961, in the Barbizon Plaza Hotel, 108 Central Park South, New York City.

The topic for the morning session is "Sex and Aging." Discussants: Dr. Harry Benjamin, Dr. Lissy F. Jarvik, Dr. Joseph T. Freeman, Mrs. Donald Armstrong. Chairman: Dr. Hugo G. Beigel.

The topic for the afternoon session is "Sex Factors in Schizophrenia." Discussants: Dr. Bernard C. Glueck, Jr., Dr. Jules D. Holzberg, Dr. Lothar B. Kalinowsky, Dr. Sandor Rado. Chairman: Dr. Franz J. Kallmann.

THE NEUROSURGICAL SOCIETY OF CHILE.—Officers of the Society for the period 1961-62 are: President, Dr. Mario Contreras V.; Elected President, Dr. Juan R. Olivares; General Secretary-Treasurer, Dr. Juan Fierro M.; Directors, Dr. Reinaldo Poblete G., and Dr. Manuel Donoso C.

NOTICE TO DIPLOMATES OF THE AMERICAN BOARD OF PSYCHIATRY AND NEUROLOGY, INC.—The American Board of Psychiatry and Neurology, Inc. requests each diplomate to maintain his current mailing address and current professional appointment on file in the Executive Office. If your address and professional appointment have changed since the date of your certification, please forward such information to: American Board of Psychiatry and Neurology, Inc., 102-110 Second Ave. N.W., Rochester, Minn.

Because of the ever increasing inquiries addressed to the Board, it has become essential to maintain an up-to-date address file on all diplomates.

David A. Boyd, Jr., M.D.,
Executive Secretary-Treasurer.

LEGISLATION AFFECTING MENTAL HEALTH PROGRAMS IN THE SOUTHERN STATES.—The Southern Regional Education Board reports on state legislation at the 1961 sessions of the legislature in 7 of the 13 SREB states that hold legislative sessions during 1961, dealing with mental health.

Arkansas: Proposed bond issue, \$16 million for new buildings at State Hospital and Children's Colony. . . . Operating fund for Children's Colony doubled for coming biennium. . . . Child guidance clinic established at University Medical Center to diagnose minimal brain damage.

Georgia: Increased appropriations for Milledgeville State Hospital and Gracewood State School. . . . Bill on determining possible increase patient-pay revenue.

Louisiana: Appropriations increased for all mental health services, with special attention to exceptional children. . . . Evaluation center for mentally retarded to be built in New Orleans, and research and rehabilitation center to be established.

South Carolina: Appropriations increased for mental health program. . . . Consultant in mental retardation added to Mental Health Commission. . . . Community health services plan enables counties to participate in mental health services on matching funds basis. . . . Psychiatric residency for South Carolina State Hospital.

Tennessee: Appropriations for mental health activities increased 23% for next biennium. . . . NIMH, Peabody College and Tennessee-Kentucky Mental Health Departments cooperate in pilot program in training of "emotionally" disturbed children. . . . New intensive treatment centers in Chattanooga and Memphis, the latter to be teaching hospital for University of Tennessee Medical School. . . . \$2½ million authorized from treasury surplus for improving mental health facilities.

West Virginia: New training center for psychiatric nursing at Huntington State Hospital. . . . Barboursville State Hospital converted to alcoholic treatment center. . . . Training school for retarded children opened to blind and deaf patients. . . . Operations appropriations for all institutions increased.

Report on the other 6 SREB states to follow when their legislative sessions have adjourned.

ENCYCLOPEDIA OF THE SOCIAL SCIENCES.—Announcement has been made that work on a new edition of this Encyclopedia has begun under the editorial direction of Bert F. Hoselitz. The plans call for an edition of 12 to 15 volumes with a total of 6 to 7 million words. Simultaneous publication of the entire work is tentatively scheduled for 1965.

The Encyclopedia will encompass the work in anthropology, economics, political science, psychology, and sociology as well as related material in social history, education, business administration, linguistics, law, and medicine including psychiatry.

The work will be under the guidance of an editorial board of social scientists from many nations under the chairmanship of W. Allen Wallis, Dean of the Graduate School of Business, University of Chicago, with consultants from all relevant fields.

The office of the Encyclopedia is at 5836 Greenwood Ave., Chicago 37, Ill.

NEW JERSEY PSYCHOANALYTIC ASSOCIATION.—The following physicians were elected to office at the annual meeting of the Association: John E. Hughes, M.D., East Or-

ange, N. J., President; Samuel A. Weiss, M.D., East Orange, N. J., Vice-President; Benedict J. Bernstein, M.D., Maplewood, N. J., Secretary; Howard Schlossman, M.D., Englewood, N. J., Treasurer; Herman Shlionski, M.D., Montclair, N. J., Council Representative; George Zavitzianos, M.D., Tenafly, N. J., Alternate Council Representative.

MEDICAL HYPNOSIS.—A graduate course in medical hypnosis is offered to physicians and dentists by the University of Pennsylvania Graduate School of Medicine, Department of Neurology and Psychiatry, beginning October 4, 1961. The course meets recommendations made by the American Medical Association's Committee on Hypnosis.

The course will be given at the Institute of the Pennsylvania Hospital, 111 North 49th St., Philadelphia, under the direction of Lauren H. Smith, M.D., Professor and Chairman of Psychiatry, Department of Neurology and Psychiatry, Graduate School of Medicine and Physician-in-Chief, Institute of the Pennsylvania Hospital. Enrollment is limited to 24. Tuition \$375.

OPEN WARDS—NEW YORK STATE HOSPITALS.—Two institutions under the New York

State Department of Mental Hygiene have achieved 100% open ward policy. They are St. Lawrence State Hospital and Syracuse Psychiatric Hospital.

Other institutions in the state, more than 90% open are: Hudson River State Hospital (92), Newark State Hospital (94), and Syracuse State School (91).

SOUTHERN PSYCHIATRIC ASSOCIATION.—The 1961 annual meeting of the Southern Psychiatric Association will be held in New Orleans at the new Royal Orleans Hotel Oct. 1, 2, 3.

The registration fee, \$15, will entitle members to the following: cocktail party and entertainment Sunday night; cocktail party, banquet and dance Monday night.

Dr. John Bick is in charge of the scientific program and Dr. Kenneth Ritter is chairman of the program committee. The nominating committee, Dr. Dexter Bullard chairman, will nominate the following slate of officers for 1961-62:

President—Titus Harris, M.D.

President-Elect—Richard Proctor, M.D.

1st Vice-President—Robert Webb, M.D.

2nd Vice-President—William Reese, M.D.

Secretary-Treasurer—Sullivan Bedell, M.D.

Board of Regents—Levin Magruder, M.D.

COMPLEMENTARY

We are foolish, and without excuse foolish, in speaking of the superiority of one sex to the other, as if they could be compared in similar things! Each has what the other has not; each completes the other; they are in nothing alike; and the happiness and perfection of both depend on each asking and receiving from the other what the other alone can give.

—JOHN RUSKIN

BOOK REVIEWS

PSYCHIATRIE DER GEGENWART—FORSCHUNG UND PRAXIS. Band 2 Klinische Psychiatrie. Edited by H. W. Gruhle, R. Jung, W. Mayer-Gross and M. Mueller. (Berlin and Heidelberg: Springer-Verlag, 1960, pp. 1229, 146 ill.)

This is the second of three volumes destined to give a picture of present-day psychiatry. The volume deals only with clinical psychiatry. The presentations, appreciations and criticisms move from the still so-called "endogenous psychoses" over psychopathies, neuroses, addictions, organic psychoses and brain diseases to psychiatry of the child, adolescent, and old people. Mayer-Gross has written a short succinct introduction. His editorial achievement is highly commendable.

Many or even most of the authors' names are as good as unknown in this country. To enumerate all of them with all their merits and demerits would bore our readers. However one and the other must be mentioned at least, if only to attract attention to their names and work. There is Wyrsch with a crisp chapter on schizophrenia the treatment of which both Max Müller and Christian Müller discuss exhaustively in an extra chapter. The manic-depressive psychoses are presented by Weitbrecht, a clinician who, rooting in the biological aspect of our field has an especially fine fingertip feeling for a philosophical approach. His chapter is followed by the therapeutic one done by Hans-Hermann Meyer who remains refreshingly critical. The symptomatic psychoses are dealt with in a structural manner with gestalt psychological leanings by Klaus Conrad. Weitbrecht and Conrad impress this reviewer particularly since they bring new ideas into an area in which some people think no new crops can be harvested. Scheid reports on a variety of disturbances in infectious and tropical diseases about which little or even nothing was known before. He also sketches the treatment of neurolues. The outstanding institution for epileptics in Bethel (near Bielefeld) is the inexhaustible source of two thorough chapters by Schorsch on clinic and research, and Dreyer on treatment of the epileptic diseases. From Waverley, Massachusetts, comes a most welcome contribution on the oligophrenias by master Benda himself.

Stutte gives a picture of the serious and less serious disturbances in children and youngsters. Ruffin takes pains to distinguish between normal aging and the un blessings of senility.

All in all, this is a book written by persons who know their business, who have a mature attitude toward theory and practice. It should be emphasized that in the German-speaking parts of Europe¹ the interest in psychotherapy has definitely increased; one can say that in this direction the influence of U. S. A. psychiatry is unmistakable. Psychoanalysis does not and never did play the role it did and partly still does play in this country. Perhaps the more theoretical training and performing withholds these outbursts of therapeutic enthusiasm which we are witnessing in our country once in awhile. Of course—and this is of more than psychiatric significance—the European attitude in general has taken on a more pessimistic streak. Whatever the degree of optimism and pessimism in respect to psychiatric treatment may be on either side of the Atlantic, the possibility of a good, mutual understanding is higher than ever before. In a sense this is implied in a remark made by Weitbrecht (p. 78): One cannot say that Kraepelin's system was everywhere accepted and kept in use without antagonism. Yet wherever there is any scientific psychiatry, one talks about manic-depressive and schizophrenic psychoses. Kraepelin's classical positions are so well known that one can come to some agreement as to what kind or psychoses one is discussing notwithstanding the most various nosologic hypotheses.

EUGEN KAHN, M.D.,
Houston, Tex.

THE JEFFERSON-DUNGLISON LETTERS. Edited by John M. Dorsey. (Charlottesville, Va.: University of Virginia Press, 1960, pp. 120, portrait.)

There are presented in this book for the first time in print the letters between Thomas Jefferson and his physician, Dr. Robley Dunglison, during a year ending just short of 3 months before Jefferson's death. The letters have to do with Jefferson's failing health and the University of Virginia that he had just founded (opened March 7, 1825) at Charlottesville and of which he was Rector.

Dr. Dorsey's annotations throughout add much to the understanding of this series of letters. The Editor has rendered a very real service in bringing this correspondence together and producing this valuable document.

¹ There are 8 Swiss authors among the 22 contributors to this volume.

Jefferson had the same high ambitions as to the quality of the teaching staff of his university and the medical faculty connected with it as Johns Hopkins, 50 years later, prescribed to his trustees for the medical school he proposed to establish. For the University of Virginia Jefferson had written, "We have determined to receive no one who is not of the first order of science in his line; and as such in every branch cannot be obtained with us, we propose to seek some of them at least in the countries ahead of us in science, and preferably in Great Britain, the land of our own language, habits and manners."

Robley Dunglison was an import from London. Of him, as Dorsey notes, Osler said, "Dunglison has all the wisdom of his day combined with a colossal industry." He became professor of anatomy and medicine and eventually chairman of the faculty of medicine at the University of Virginia. Later on he was invited to Philadelphia where he was made professor of the Institutes of Medicine at Jefferson Medical College. He authored several medical texts, including his highly regarded textbook *Human Physiology*. He has been called the "Father of American Physiology." He is perhaps best remembered by his famous medical dictionary, the first edition of which came out while he was at Charlottesville. The Dunglison Medical Dictionary was a standard reference work through 23 editions.

An interesting debate between Jefferson and his physician occupies several of the letters in this book, couched in the exquisite language of gentlemen of the time, concerning payment for the doctor's services. The patient continued insisting and the doctor continued to refuse.

As the spring of 1826 drew on Jefferson was fully aware that the end was near. Even 7 months before his death he had spoken of "the fragment of life remaining to me." During the evening of July 3, arousing himself momentarily and seeing his faithful doctor at his bedside he asked, "Is it the Fourth?" Dunglison replied, "It soon will be." And on the morrow, while everywhere the 50th anniversary of the Declaration of Independence was being celebrated, about midday its author died.

C. B. F.

THE DAY HOSPITAL MOVEMENT IN GREAT BRITAIN. By James Farndale. (New York: Pergamon Press, 1961, pp. 430. \$15.00.)

"Part-time hospitalisation" is now an important means of psychiatric treatment, and is the product of a number of forces, both medical and social.

Effective treatment exists for most acute

illnesses in the younger age groups, and can often be given outside hospital. On the other hand, there are enormous problems of chronic illness in the older groups, which are unlikely to respond to curative measures, but which may need intermittent help over a long period. At the same time, complex modern treatment and rising living standards have caused an alarming rise in the costs of hospital care, and an increasing deficit of nursing and ancillary staff.

In answer to these developments, it seems necessary to give up the existing rigid conceptions of inpatient and outpatient treatment. From this point of view, there are many patients who do not have to accept board and lodging in hospital, simply because they are undergoing investigation or treatment there. It would also seem essential to break down the segregation between medical care in hospital and that outside.

All these factors apply, *par excellence*, to the problems of psychiatric illness, where, as Cameron has pointed out, treatment is not simply the mechanical application of specific cures, but a process of modifying behaviour. This process requires more than the conventional facilities of a hospital. It demands a continuous series of treatment settings, all of which are interdependent, and all in close touch with the community.

Many of these facilities will necessarily be "part-time," and one of the most useful of them is the day hospital, where services can be tailored to the needs of every individual patient. There has been much discussion on this subject in recent years, but some has been highly speculative, and some merely wishful thinking.

In contrast, Mr. Farndale's book is an admirably objective record of what actually exists in Great Britain, in the field of day care. As a hospital administrator, he set out to discover what facilities of this sort were available, in 1959, for psychiatric and geriatric patients. He visited over 60 hospitals and centres, and describes what he found there in exhaustive detail.

This trend of day care is shown to have erupted in widely differing forms throughout the country. Though there is national planning of the medical services, local initiative and individual personalities still seem to be decisive in creating these units. There is every stage of development, from an independent day hospital with separate staff and services, to informal arrangements for patients to spend the day at the occupational therapy department of a local hospital.

The 1,500 psychiatric day patients, who were attending at this time, form a very small number, in comparison with the 200,000 hospital beds for mental illness and subnormality, or the vast numbers of outpatients. However, it is clear that these day facilities are widely appreciated, and that large-scale expansion is planned for them.

It was premature at this stage to make predictions about reductions in hospital beds, but Farndale points out that by no means all day patients would otherwise be candidates for admission. To some extent, they form a "new clientele"—which is one equally meriting treatment.

He is well qualified to discuss the important financial implications of day treatment—though in Britain, these are not the immediate concern of the patient. There seems to be opportunity for some capital saving, in providing day places rather than inpatient beds—the cost is probably less than a third. However, comparison of the costs per patient in the two settings is more difficult, since the standards of treatment provided may be entirely different. This discussion underlines the unsatisfactory nature of hospital costing in psychiatry on a weekly basis, rather than that of a "patient-illness."

Farndale's conclusion is that, if additional money is to be spent on improving mental health services, the provision of more day hospitals would be one of the most economical and socially satisfactory ways of achieving the object. This seems fully justified by the evidence provided.

This book is not uniformly satisfactory, particularly as the medical aspects have to be reproduced at second-hand, and psychiatrists will certainly have more to say on the question. The style does not encourage easy reading and some of the profuse illustrations are of rather doubtful relevance. However, all those who are concerned with the operation or planning of day hospitals will find this an invaluable work of reference.

HUGH FREEMAN, B.M., D.P.M.,
Littlemore Hospital, Oxford, England.

CULTURE IN HISTORY: ESSAYS IN HONOR OF PAUL RADIN. Edited by Stanley Diamond. (New York: Published for Brandeis University by Columbia University Press, 1960, pp. 1014. \$15.00.)

Paul Radin (1883-1959) was one of the most original and formative influences in American anthropology. This *Festschrift* in his honor contains 54 contributions, far too numerous to list by author and title, but covering the whole range of Radin's interests. To summarize the

common theme of these contributions is not difficult, for almost all of them are characterized by an interest in the human mind at work, and hence will be of particular interest to readers of this Journal. This is not an ordinary *Festschrift*, it is an extraordinary one, dedicated to the memory of a great man and a distinguished teacher who, although he did not work well in harness, as a free spirit helped to free the spirit of others. Radin died shortly before he could receive this volume in his honor. It will always remain a testimony to the humanizing influence he exercised in his chosen field. His own writings, happily, grow in stature and in appreciation with the progress of time. This, perhaps, more than anything else indicates the true measure of the man.

ASHLEY MONTAGU, Ph.D.,
Princeton, N. J.

THE HEALTHY CHILD. Edited by Harold C. Stuart and Dange G. Prugh. (Cambridge: Harvard University Press, 1960, pp. 507. \$10.00.)

This excellent book is written by 22 experts who provide conceptual background material for professional participants in health, psychological, social and educational services for children. Every phase of growth and development is covered, and the purpose of the book to increase the application of general principles is well realized in a highly readable text. There is a valuable group of section references and notes at the end of the book, and an index.

ASHLEY MONTAGU, Ph.D.,
Princeton, N. J.

THERAPEUTISCHE FORTSCHRITTE IN DER NEUROLOGIE UND PSYCHIATRIE. Edited by Hans Hoff. (Vienna, Austria: Urban & Schwarzenberg, 1960, pp. 510. Schilling 318,— or DM 53.—.)

With the collaboration of some 34 scientists, the author (who heads the department of psychiatry at the University of Vienna and whose monumental work, *Lehrbuch der Psychiatrie*, was previously discussed here) primarily offers the reader clinical and dynamic evidence of the close relationship between neurology and psychiatry. This, at first thought, may not sound new. However, in practice, there are probably few readers who would not agree with the author that neurologists and psychiatrists do not actually have the close relationship that one would expect; both "specialties" are even completely separated in most clinics and hospitals. The book is divided, intentionally and not arbitrarily, into two logical parts, namely Neurology, and Psychiatry. However, most of the

contributions under Neurology are written by psychiatrists, and most of the contributions under Psychiatry are written by neurologists. That alone should give food for thought here and abroad! Some chapters in both parts are written by the same author, such as those by Hans Hoff on the neuropsychological basis of modern neurology in the first part, and those on the progress in psychosurgery in the second part. Each contribution is skillfully edited and supplemented with lengthy appendices of bibliography from both hemispheres!

HANS A. ILLING, Ph.D.,
Los Angeles, Calif.

PSYCHIATRY: DESCRIPTIVE AND DYNAMIC. By Jackson A. Smith. (Baltimore: The Williams & Wilkins Company, 1960, pp. 342. \$7.00.)

In the preface the author states: "The aim of this book is to describe concisely the various syndromes seen in psychiatric patients and to make these syndromes recognizable to student and physician alike. . . The prevailing dynamic concepts are included, as well as a brief review of their origins. Theoretical differences between the founders of different schools of psychiatry are mentioned."

Chapter 2 deals with Schools of Psychiatry and has interesting accounts of Jung, Adler, Ferenczi, H. S. Sullivan, Karen Horney and existential analysis. Sigmund Freud does not appear nor does Adolf Meyer. Charcot, Kraepelin, Bleuler, and Janet are given short write-ups in Chapter 1, "History of Psychiatry," which presumably explains their omission under "Schools of Psychiatry." With the exception of existential analysis, schools of psychiatry apparently are only those that are commonly regarded as Freudian or neo-Freudian.

Chapter 3 is labeled "Psychodynamics" and it is stated, "This material generally follows the concepts defined by Freud. Where the theories of others are included, the author's name is given." This chapter contains 29 pages and seems to be a fairly good but brief presentation of Freud's view.

It is difficult to assess this volume. In general it is clearly and simply written and some parts of it are excellent. Apparently the author feels that psychodynamics is adequately covered by Freud's theories. The reviewer finds it difficult to understand how an American textbook could be written with chapters on "History of Psychiatry" and "Schools of Psychiatry" which only mentions Adolf Meyer briefly in the chapter on "Affective Reactions," stating that he suggested that the term melancholia be abandoned in favor of depression, and that

further distinction could be made in accordance with the intrinsic nature of the depression. Under "Schizophrenic Reactions" there is one page devoted to some of Meyer's ideas.

It is not clear for what group this book is written. It is too brief and has too much of importance omitted to serve as a textbook in medical schools. It does not seem that this book will be particularly valuable to the psychoanalysts as the material given is very limited and contains nothing new. It is perhaps most fitted for popular reading because of its simple formulations and the ease with which it is understood.

KARL M. BOWMAN, M.D.,
San Francisco, Calif.

JAHRBUCH DER PSYCHOANALYSE. Beitrage zur Theorie und Praxis. Vol. I. Edited by K. Draeger, H. E. Richter, G. Scheunert, and E. Seeger. (Cologne, Germany: Westdeutscher Verlag, 1960, pp. 297. DM 25.—.)

The Preface was written by Anna Freud in London, as a send-off for the *Wiederaufnahme* of the Annual Proceedings of Psychoanalysis and the *Wiedererstehen* of the psychoanalytic movement in Germany. However, many of the contributors seem to this reviewer to suggest the analogy of carrying coal to Newcastle: Karl Menninger writes on "Regulatory Devices of the Ego under Major Stress," now translated into German from the *International J. Psychoanalysis*, as "Ich-Veraenderungen"; or Michael Balint (London) has translated a paper, originally presented to the Inaugural Meeting of the Pittsburgh Psychoanalytic Society, as well as subsequently at Society Meetings in London, Montreal, New York, and Washington 1959/1960, entitled *Primarer Narzissmus und Primare Liebe* (Primary Narcissism and Primary Love). There are also papers by Therese Benedek (New York) on *Elternschaft als Entwicklungsphase* (Parenthood as a Developmental Phase), discussing Freud's libido-theory, J. Lampl-De Groot on "Depression and Aggression," A. Reich (New York) on "Comments about Counter-transference," Erich Simenauer (South Africa) on "Psychoanalysis and Surgery"; or Paul Parin's "Counter-transference and its various forms of Resistance." While the *Jahrbuch* makes its first appearance and contains valuable contributions, its indices are poor or non-existent, but it can be hoped that subsequent Proceedings will contain more "home-grown" products. But a new "baby" is always welcome!

HANS A. ILLING, Ph.D.,
Los Angeles, Calif.

PSYCHIATRY AND LAW:
USE AND ABUSE OF PSYCHIATRY IN A MURDER CASE¹

FREDERICK WISEMAN²

The murder case I shall discuss illustrates rather dramatically many of the current problems in the inter-disciplinary field of psychiatry and law. As you read this case study I would like you to consider 3 principal points: 1. Psychiatric expert testimony is too complex, both emotionally and intellectually for a jury and judge to understand, accept and use to make a just disposition of a particular case; 2. The technical phrasing of the legal test of criminal responsibility is less important than the attitude toward crime represented by the test; 3. The courtroom confrontation of psychiatrists with different theoretical orientations leads only to chaos, disrespect and interference with the needs of the community and the disposition of the unique problem of each offender.

On April 20, 1957 at 1:15 p.m., Jim Cooper, a 23-year-old airplane mechanic from Roxbury, Mass., walked into the hallway of an apartment house in Brookline, Mass. His former fiancé Connie Gilman lived in the second floor apartment with her parents. Cooper stopped in the hall and released the safety latch on the Belgian automatic .38 in his pocket, climbed the stairs and rang the Gilman's bell. He took the gun out as Connie opened the door. She saw him standing waiting in the hallway with the gun in his right hand. Their eyes met. Cooper said to himself, "Jim, shoot, shoot." He couldn't pull the trigger. Connie slammed the door. Cooper shut his eyes and shot and shot, 9 times. He ran out of the house and after telling a policeman four times that he had committed murder finally

convinced the officer to take him to the Brookline Police Station. Later when asked by a detective whether he fired with intent to kill, Cooper said, "I fired to blow her fucking head off. How many times do you want me to tell you?" At another time he said, "After it happened, I didn't even seem to realize what it was—it didn't seem real, I never saw her actually get shot; I never seen the bullet enter her body; I said, 'This didn't really happen.' But I knew it did . . . I thought, 'Jim you must have killed her.' I didn't know, but I thought I must have. It just seemed to me that all my life I was bound to end up in the chair. If that was the way it was, that was the way it would be."

Cooper met Connie Gilman in 1949 when he was 16 and she 12. They became engaged in 1954 when Cooper was in the Air Force. Connie and Jim exchanged wedding rings and made plans to be married. However, as often as the plans were agreed on Connie changed them, frequently at her mother's insistence. She always said, "Yes," and then, "No." After Cooper's discharge from the Air Force in 1956 he went to work in California and the yes-no pattern continued. Finally, in April 1957 Cooper came to Boston determined to marry Connie or get his ring back. Connie and her mother were reluctant to return the ring. Cooper was later to describe his feelings at that moment saying:

I became very upset at that time. I recall Connie saying, "Jim you're all red." I didn't say anything. At that time I had the idea that it was an utterly hopeless and solutionless and impossible situation which I had become entangled in and that I wanted to kill Connie Gilman. I fought this emotion down, kissed her goodbye, walked out of the house. I said, "Jim, you better get drunk. You'd better get good and drunk, not just happy and sad, completely comatose." So I got in the Chevrolet that I had rented and drove to a bar somewhere in the vicinity of

¹ Read at the 117th annual meeting of The American Psychiatric Association, Chicago, Ill., May 8-12, 1961.

² Lecturer-in-Law, Boston University Law School, Boston, Mass.; Russell Sage Foundation residency, Dept. of Social Relations, Harvard University.

Kenmore Square. I went into the bar and had two shots of bourbon; took off my jacket. I remember I stared at some middle-aged women sitting there, staring directly at me. I felt, "Well, even that woman there doesn't even know you. She realizes what a big chump you are." And I thought of how Mrs. Gilman thought what a big chump I was, and how Connie either thought that or was using me. And I said, "This is the end." I went out to the car; I took my gun out of the glove compartment, put it in my jacket pocket, drove back to the house, parked the car. I got out of the car and started to cross the street and a number of ideas passed through my head. First, "I am going to kill her; I am going to put this gun right up against her forehead and pull the trigger and then I shall do the same for myself."

Second, the second was, "Jim this is foolish, there must be some kind of a solution. She said that she would get the ring out of the bank on Monday." And I thought, "Yes, she did." She also knew that my plane was leaving the airport at 7:00 on Monday morning and I would not be in Boston in time to get the ring.

And if she really wanted to give me the ring, she would have already done so. And if I waited until Monday, lost another day of work, she would probably give me some kind of stall or excuse again. And I then thought, "Jim, you don't really want to die, do you?" And I said, "No." And I said to myself, "But you are going to let them get away with it?" And I says, "No." I said, "Do you realize if you do this they will electrocute you?" And I said, "Yes."

And then I thought of my father. I do not know why, it just shot through my head for a minute. And I came to the conclusion that that was exactly what I deserved, and that it fitted in with the idea that I have always had, that I would never live to be 30 years old and that I had adopted the attitude while in the service: live fast, die young, and have a good-looking corpse. . . .

I suppose all of you are familiar with the legend of King Midas. If you recall, he was a man who, that everything he touched would turn to gold . . . let us say that my name is King Shitus.

These brief quotations will, I hope, give you some sense of the man who killed this girl.

In a period of 17 months Cooper was seen by nine psychiatrists and three psy-

chologists as well as a series of social workers representing various state agencies. The purpose of this paper is: 1. To discuss and evaluate the variety of purposes served by psychiatric expert testimony in the pre-trial, trial and post trial phases of this murder case; 2. To offer some general comments about present and proposed relationships between law and psychiatry.

PRE-TRIAL

The first contact between law and psychiatry occurred when by Court order Cooper was sent to the Bridgewater State Hospital for a 35-day observation period. He was returned to the jurisdiction of the Court and the examining psychiatrist wrote in his report to the judge,

No evidence has been elicited that he is insane. Memory, judgment and insight are intact and he is not deluded. It is the opinion of the staff that he is not insane and is responsible for his conduct. His return to Court for disposition is therefore recommended. Diagnosis: Without Psychosis-Emotional Instability.

The next step in the State's psychiatric assessment of Cooper was the Briggs Law examination. This now famous statute, passed in part to avoid a court-room battle of experts requires that an examination be conducted of an accused in capital cases, "with a view to determine his mental condition and the existence of any mental disease or defect which would affect his criminal responsibility." The Commissioner of Mental Health appointed two state hospital superintendents as the Briggs Law Examiners. Their findings, submitted on a form prepared by the State for this purpose, were meant apparently to contribute to the understanding of this man. They reported to the Commissioner:

Report To Department of Mental Health
(On mental examination of prisoner under Section 11A, Chapter 123, General Laws.)

Habits: Alcohol

Drugs: Use denied

Sex: No abnormality noted

Social Adaptability and Interest in Social Life:
Feels he is quite sociable and gets along well in general but quick tempered. Likes to attend beach parties, house parties, and dancing. Interested in modern music.

Psychiatric Findings :

Subject was cooperative to interview in general. He handled himself well and was aware of the seriousness of his situation and understood his legal rights. He was normally productive. No evidence of depression or other mood disturbance. No hallucinations or delusions elicited. No evidence of psychosis. Psychological tests show C.A. 23 years, M.A. 18 8/12 years, I.Q. 1.04. Subject is not insane or mentally deficient.

State Definitely Whether in the Opinion of the Examiner, the Prisoner is Suffering from Any Mental Disease or Defect which Would Affect His Criminal Responsibility :

In our opinion, the prisoner is not suffering from any mental disease or defect which would affect his criminal responsibility.

The effect of these State ordered psychiatric examinations was that Cooper was competent to be prosecuted as a normal murderer.

Cooper admitted the murder. Yet, by law, he had to plead "not guilty" once the State determined he was competent to stand trial. In Massachusetts the test of criminal responsibility is a combination of M'Naghten and Irresistible Impulse. The State-appointed defense counsel had to present evidence that Cooper did not "know the difference between right and wrong" and/or was not able to "resist the impulse to kill." This kind of a defense could only be made through psychiatric expert testimony. Cooper's counsel sought assistance from senior members of the Boston psychiatric community but was unable to successfully solicit their interest in the case. After considerable effort defense counsel succeeded in finding a psychologist and 2 young psychiatrists who were willing to serve as defense experts. The two psychiatrists saw Cooper and submitted written reports to defense counsel. One wrote :

I see no evidence that this patient is not aware now or was not aware at the time of the murder of the nature and consequences of his destructive acts. However, it is apparent that he has been suffering from a personality disorder characterized by a low tolerance to frustration and behavior which would bring about immediate gratification to his instinctual needs. This behavior has at times been antisocial in nature and the patient has felt little conscious remorse or guilt about these acts, especially

the recent murder of his girl friend. On the other hand, there is evidence that since age 9 he has been subject to a pathological drive to be punished for the accidental death of his father for which he has unconsciously, and sometimes consciously, felt responsible.

If this man had been brought to a psychiatrist at any time since . . . age 12 it would have been evident that he was definitely in need of psychiatric help.

Formal Diagnosis : Personality Disorder.

The defense psychiatrists unlike the Briggs Law Examiners included in their reports accounts of some of Cooper's feelings and experiences which, isolated from the rest of his life, provide some understanding of the emotional problems that led to the murder. Cooper's father died when the boy was 9. Mr. Cooper slipped on the ice chasing his son insisting he wear a warm cap on his way to Hebrew school. Cooper felt he killed his father. Afterwards, there were many self-defeating and destructive acts connected, in one way or another, with these feelings. As a 12-year-old he swallowed iodine rather than go to Hebrew school ; at 15, he was badly bruised when he insisted on fighting 5 boys who attacked him swinging garrison belt buckles. Also, at 15 a B-B pellet pierced his right eye when he and another boy were playing with a gun. In the Air Force a buddy saw him with a pistol pointed at his head and talked him out of the suicide attempt. In Boston on leave from the Air Force he fought with another of Connie's suitors and spent 2 weeks in hospital with a broken nose. As an Air Force mechanic Cooper felt guilty about the death of two pilots despite the fact that an Air Force investigation determined their death was due to pilot error rather than mechanical defect. Also, the defense psychiatrists pointed to another incident that tragically demonstrated Cooper's inability to handle his feelings. One time a stranger began to annoy a girl he was with, but Cooper, unable to tell the man to go away, contained his rage and anger until, bursting, he whacked the stranger over the head with an empty beer bottle.

The second defense psychiatrist confirmed his colleague's pre-trial diagnosis and wrote, "I do not believe he (Cooper) can be

labelled a psychotic." The defense psychiatrists were convinced that Cooper was an emotionally sick human being badly in need of psychiatric treatment and that the murder was a violent expression of his illness.

The defense counsel had to proceed with the trial knowing his client to be a very sick young man but aware that under the existing legal standards Cooper's behavior, the murder, of course, aside, was probably not sufficiently bizarre to qualify him for a M'Naghten acquittal.

TRIAL

A jury of men and women were asked to listen to the psychiatric assessments of Cooper and reach their decision on the issue of his "responsibility." This charade was built on the myth that the jury was capable of absorbing, understanding and acting on a complex psychiatric explanation of the murder as well as evaluating the differences in point of view revealed at trial.

The first defense psychiatrist testified that Cooper was suffering from a mental illness which he defined as, "an abnormal variation of a person's mood and abnormal variation of a person's thinking processes or an abnormal variation of a person's behavior." The judge excluded any testimony that Cooper had been in need of psychiatric help since age 12. In an effort to fit the "irresistible impulse" test requirements the psychiatrist testified, "that this man was in a state of great emotional tension, that he was obsessed with the need to obtain some decision from Connie Gilman . . . he was obsessed with either getting the ring back, or getting her to marry him, or getting her to give some definite opinion about their status."

In this adversary proceeding the State had to rebut this testimony and make its case that the murder was "premeditated," that Cooper knew "right" from "wrong" and that he did not commit the murder under the pressure of an irresistible impulse. The prosecuting attorney tried to lead the defense psychiatrist to these conclusions while simultaneously discrediting the direct testimony.

This defense psychiatrist had written in his report to defense counsel that, "At no

time did he (Cooper) express regret that her life had been interrupted." The State's Attorney reasoned that if Cooper did show regret then he would know that his act was "wrong" and therefore knew the difference between "right" and "wrong." He proceeded this way :

- Q. So I ask you, sir, in your opinion . . . was he or did he indicate in any way that he was sorry that he killed this girl.
- A. He did not say he was sorry he had killed this girl and he was expecting the electric chair.
- Q. Doctor. Can't you answer that question Yes or No ?
- A. I can only answer it on the basis of what I observed. I observed that . . .
- Q. What is your opinion doctor ? Was he or was he not sorry that he killed the girl ?
- A. My opinion is that he regretted killing the girl but somehow felt it was in the cards, that something like this was going to happen in his life, and that he had no control over it, and this is the way it was going to be, he was going to get the chair and here it comes.
- Q. So your answer is, doctor, that in your opinion from your examination of him he was sorry that he killed the girl ? That is true, isn't it ?
- A. I would say he was sorry but felt there was nothing he could do about it.
- Q. Doctor, are you trying to hedge on the answer ?
- A. I am trying to give you an accurate answer as to what I felt was going on in this man's mind.

The prosecuting attorney asked this witness to define personality disorder. The doctor replied in words probably only comprehensible to a person who already knew and was ready to accept a psychiatric explanation of behavior :

- A. Now, personality disorder, the identifying symptom in such a case is where someone handles their anxieties and their feelings which disturb them by action rather than having psychotic symptoms such as hallucinations, delusions, or having anxiety such as somebody who is—or phobias such as social fears and things of that kind, or is opposed to somebody who might have a disturbance of their mood in which they might be grossly euphoric or extreme depression.
- Q. Will you tell us what the personality dis-

order . . . that makes this chap mentally ill is ?

A. I feel that under the general category of personality disorder this man falls into really two types, two sub-types of personality disorder. These are : 1. Passive aggressive personality . . .

Q. Well, now stop right there. What does that mean ?

A. Passive aggressive personality refers to a type of individual whose behavior characteristically throughout their life reveals two main trends : one is a passive obstructionism ; two is overt aggressive uncontrolled outbursts. . . . Would you like me to give some examples from this case ?

Q. From this case, please, doctor.

A. I think you have heard very well described by the mother and by the sisters this man's attitude around the home. For instance, his mother would suggest that he do something and rather than tell her overtly that he would not do it, as a normal person would do, he simply went out and did something else.

Later in the cross-examination the doctor was asked :

Q. Well, now, by your statement, doctor, do you mean to tell us that this inner feeling and this problem, this deep-seated consciousness of guilt regarding the death of his father, was responsible for him going up, taking the gun out, going upstairs and killing this girl.

A. It played a great part, in my opinion, in his getting involved in an event for which he would obviously receive a great deal of punishment.

Q. Upon what theory do you base that, doctor ?

A. This is based on the common psychiatric technique of explaining a pattern of activity or a pattern of thought in the person's life by the type of events to which they were subjected, the types of stress, actual and traumatic events to which they were subjected in their younger years, and in this man's case this was an extremely traumatic event, as it would be in any child, sir.

The second defense psychiatrist supported his colleague's testimony and in an effort to span the separation between psychiatry and law testified that a, "personality disorder is characterized by impulsive ac-

tion of a very sudden onset in the particular individual concerned." Then, this confusing exchange on the meaning of the word "normal" took place. As you read this cross-examination please note the psychiatrist testifies that Cooper's behavior was consistent with his personality disorder but the prosecuting attorney tries to take this to mean that Cooper was "normal" as opposed to emotionally ill. The reference is to the beer bottle incident.

Q. Now, doctor, it is just a question of degree isn't it, because supposing we have the same set of facts and the man stands up and strikes this chap with a fist. Is he a man of personality disorder ?

A. I would say perhaps less, sir, on that particular symptom. I think there is a gradation, I agree with you, and I think people may push, people may hit, people may insult each other, may each look angry. There are all kinds of degrees, and I think where you draw the line and what you call pathological or what you call abnormal is a question of degree and one of opinion. I would consider for Cooper this was not an abnormal reaction.

Q. A normal reaction for him ?

A. For Cooper because he is a personality disorder.

Q. Would you say that was a normal action of his ?

A. I think he reacted in a typical fashion for him.

Q. Now, when you say pathological what do you mean, doctor ?

A. Abnormal . . .

Q. And what do you mean when you say abnormal ?

A. Symptomatic of mental disease.

The psychologist who tested Cooper with the Rorschach, Wechsler-Bellevue, Draw-A-Person and Thematic Apperception Tests also testified at the trial. The psychiatrists had told the jury many intimate details of Cooper's life. However, the psychologist talked of Cooper's feelings and fantasies in a complex but frank way acceptable to a case conference but perhaps inappropriate when addressed to unsophisticated jurors. On cross-examination the psychologist was asked to give illustrations of Cooper's response to the Rorschach Test. She read his response to one of the cards ;

Two mole-like creatures fighting over a blanket of cloth, trying to shoot at each other. Rays are coming out. The rays are hitting at each other and neutralizing out, and when the rays meet they form a bomb, fall into the bottom and create an uproar. These two pink colors are climbing and these rays are clashing in here and a bomb is creating this. The coloration suggests heat; it seems like two rays are hitting each other and interacting and combatting each other, generating this part and in turn producing this splitting action.

This exchange then took place :

Q. Well, will you tell us how many of these answers made you determine that he had, we will say, a depressed mood to begin with ?

A. I would say it depends on certain ratios in the scoring symbols, it just isn't done that way.

Q. Can you tell us, ma'am, how many symbols made you think he went to a high level and then became unstable, from a depressive state to an exhilarant state ?

A. I would say this depends—if I may—this is quite technical, but it would depend on what we call the CF ratios, which, the color response which have little form, if these are greater than the number of human movement responses, this is a sign of impulsivity. The degree of the number of shading responses and blacks and greys refer to the depressed sense. Again I insist I am oversimplifying. But this is the basis for coming to these conclusions.

A properly trained person might understand this explanation. A serious offer of this kind of material to a jury is farce.

The psychologist was then asked to continue her explanation of Cooper's sexual attitudes. The following testimony refers to such emotionally neutral subjects as murder, incest, impotence and sexual promiscuity. The psychologist testified :

A. His sexual problems have been touched on above but it seems necessary to point up again his anxiety about being inadequate as a male, and his attempt to seek substitute phallic symbols as some kind of compensation for his perceived superiority.

Q. Would you stop there ? Would you tell us what that means ?

A. Well, the first thing it says is that he has some doubts about his masculinity, about being powerful enough of a man, and one way of trying to deal with his feelings of

this sort is he is attracted to objects which are symbolic of masculinity and which he, therefore, is attracted to to compensate for these feelings.

Q. All right. If you will go on.

A. Thus, guns, rifles, big cars, weapons are perceived by him in very erotic, highly charged ways, and reflect among other things his attempt to assert himself as a powerful male, and protect himself from assault from others.

Q. Well, now, do I understand from that that the fact that he has a gun or that he might have a Cadillac or a big car, that that is the way to hide male impotency ?

A. That is the way to compensate for feelings of male masculine inferiority, the feelings of it.

Q. Would you say that people who have guns and that those that drive in big automobiles, that they all feel that they are impotent or they have male problems ?

A. I would not.

Later, in this cross-examination, the classical theme of incest was introduced :

Q. Will you read the last sentence ?

A. In this connection, too, there is evidence of a marked feminine identification, which is not surprising in the light of his anxiety over his incestuous wishes, and his image of masculinity as sadistic and destructive, which is too anxiety provoking for easy identification.

Q. Now, what does that mean ?

A. Well, the first thing means, and I say, "evidence of a marked feminine identification," I think that the young man who is brought up in a household of women does tend to identify, perhaps more with female-like values, characteristics and interests.

Q. Of course, isn't that a fact that anybody whose father died when he was young and had three sisters would be in exactly the same category ?

A. I would agree, "which is not surprising in light of his anxiety over his incestuous wishes."

Q. What are "incestuous wishes ?"

A. This comes from some Freudian theory about attitudes of young male children toward their mother.

Q. Well, now, where there are incestuous wishes, you are referring to incest, are you not ?

A. Not literally, no.

Q. I mean, that is the word, incestuous wishes. What do these two words mean, then, ma'am, incestuous wishes ?

A. Shall I tell you how we use it in psychiatry?

Q. Would you answer the question, please?

A. I would have to answer in that way.

Q. You may.

A. I have used the word so I must tell you how I have used it.

Q. Yes.

A. This refers to the kind of attachment that young sons have for their mother, in, oh, around 4 or 5 and 6 years of age, and this ties up with the mother in which the father is often seen as someone who gets in the way of spending all the time with the mother.

Q. So that has nothing to do with the word or with the thoughts of having incest, does it?

A. No, I didn't use it in that way.

Then in the form of, "If you knew—would that change your opinion?" questions, the State's Attorney proceeded to review Cooper's sexual experience. This line of questioning ended in the following colloquy:

Q. Assuming those facts, would that not change your opinion, as to the fact that he claimed or—your findings that he was inadequate as a male?

A. Not in the least because it is part of his whole pattern of denying his fear by doing the very thing he is afraid of.

Q. Would you explain that a little more.

A. Sure. I think it is like the child who whistles in the dark, who is terrified of jumping down from something and jumps down five times to prove that she is not afraid, and this is what I think is happening, this is what that kind of evidence would mean to me.

The Court: I don't get that. You mean the way to prove that you are inadequate sexually is to keep having sexual intercourse, or what?

The Witness: No. In order to keep proving that he is not inadequate to himself is to continue having sexual relations because...

The Court: Don't you think that would satisfy him that he was adequate?

The Witness: Well, unfortunately, I think that these things don't happen that way, that if the feeling is very deep within a person...

The Court: Have you had any personal experience?

The judge's reaction is after all only one of a number of possibilities, some of which

must have occurred to the jury. Suppose, for example, individual jurymen possessed guns, rifles, or big cars, might they fear a psychologist's similar verdict about them? They might know, for certain, that it couldn't be true for them. How, therefore, could it be true for Cooper? It is preposterous to presume that a jury is any more ready to accept and understand this kind of interpretation than any other unprepared individuals or group.

The State had to rebut this complex testimony. The State's theory was that Cooper was normal. The two psychiatrists who conducted the Briggs Law examination were called. The first, asked for his definition of psychosis, said, "Insanity, mental illness and mental disease." The defense psychiatrists had, it will be remembered, characterized personality disorder as a mental illness. The State psychiatrist then defined personality disorder in this crisp scientific language, "It means a variation in the behavior of the person from the usual behavior pattern." The prosecuting attorney then asked this simple question:

Q. Well, doctor, in relation to character disorder or personality disorder, is it your opinion as an expert that a person who has a personality disorder, does that person know the difference between right and wrong?

A. Yes.

The colloquy continued:

Q. Now I ask you specifically in relation to this defendant, doctor, what was your conclusion after receiving from him his history and the examination of him as to his insanity or being sane at the time you examined him?

A. I felt that he was perfectly sane and had not mental illness or a psychosis. His mood was normal. It wasn't depressed. It wasn't exhilarated. His memory was normal in every way. He had no delusions or hallucinations. His attitude with us was normal, cooperative, friendly. His intellectual capacity was tested and found to be normal.

Q. Now, doctor, I ask you, have you formed an opinion as a result of your examination as to what his condition was on the day of the crime, April 20th, this year, sir.

A. In my opinion he was perfectly sane at that time and had no mental illness.

Q. When you say he was perfectly sane, I ask you whether at that time, in your opinion, he knew the difference between right and wrong, doctor.

A. Yes, he did.

The other Briggs Law Examiner confirmed his colleague's testimony. The two Briggs Law experts testified that together they had done a mental status examination of Cooper during a single interview of one hour and ten minutes. In their court appearance one doctor testified that he knew the father died when Cooper was 9 but did not know the circumstances of death, the other said he did not recall asking whether the father was dead or alive. One testified that he knew of the gang beating, the other said he knew nothing of it. One testified that he knew of the fight over Connie which resulted in a broken nose and hospitalization, the other said he knew nothing of it. One testified that Cooper had told of the near-suicide attempt in the Air Force, the other said he knew nothing of it. One testified that he knew of Cooper's guilt over the death of the pilots, the other said he knew nothing of it.

This concluded the presentation of psychiatric expert testimony.

The judge charged the jury along the classic M'Naghten, Irresistible Impulse lines. Theoretically, this was meant to help the jury understand the psychiatric expert testimony and its relation to the tests of criminal responsibility. One way of estimating how much of the testimony the jury understood is to examine the degree of comprehension shown by this experienced jurist. In the course of his charge the judge reviewed the qualifications of the expert witnesses. The psychologist testified that she received a B.A. degree from Brooklyn College in 1945 and a Master's and Ph.D. in psychology from Cornell University. The judge in his charge said,

We had another witness who was not a doctor of medicine, but she has a Doctor's degree. I do not know whether it is in psychology or philosophy. But she is a doctor and has a Master's degree, and she has been out of college longer than the doctors. She got through college in 1948. Took up the study of psychology which is the study, of course, of the human mind.

In discussing the testimony of the second defense psychiatrist, the judge commented :

Dr. . . . said that the defendant is suffering from a severe mental disease and the particular disease that he is suffering from is a personality disorder. He gave—I think you recall, and if you don't why pay no attention to what I say—he gave a different meaning to personality disorder than some of the other doctors. He said, "Personality disorder is characterized by impulsive action of a very sudden onset in the particular individual concerned. There are many features of this particular illness which, if I may, I would like to read." But he was not allowed to read them, of course, because we were to listen to his testimony as to which he could be cross-examined, and not what somebody had written in a book, somebody of whom we know nothing at all. Now, of course, the fact that a person is highly emotional, suffers from a personality disorder, was defined by others as you would probably define it. A departure from the normal behavior pattern does not excuse a person for killing another person. But, as I have said, Dr. . . . used the words in a different sense and it is to his—and, of course, you consider the meaning he gave the words in considering his testimony—a personality disorder, he spoke of, as characterized by impulsive action of a very sudden onset in a particular individual—and if you give weight to that opinion, if you believe that, you may consider it of importance in determining whether the defendant there was suffering from an irresistible impulse. Whether he was under a compulsion to kill that he could not resist.

The judge had no difficulty in recounting the testimony of the State's psychiatrists for they had testified that Cooper was "perfectly sane." The judge, in summarising, quoted the testimony of one State expert :

He felt that he was perfectly sane and had no mental illness or psychosis. His mood was normal and he was not depressed and was not exhilarated ; his memory was normal in every way ; he had no delusions or hallucinations. And his attitude with us was normal, cooperative, friendly. His intellectual capacity was tested and found to be normal.

The fact that Cooper's motive for killing Connie Gilman was complex and obscure and probably difficult even for the psychiatrically-trained person to understand made

no difference. The jury was supreme. For as the judge said :

That question whether that mental disorder was insufficient to excuse him from crime or sufficient to excuse him from crime is not to be decided by expert witnesses, but is to be decided by you, getting any help you can from the expert witnesses and from what you yourselves have observed as the defendant testified.

When the judge concluded his charge, Cooper made a statement to the Court and jury saying, "It is my opinion that any decision other than guilt, guilty of murder in the first degree, with no recommendation for leniency, is a miscarriage of justice."

The jury, asked to correlate the testimony with the definition given in the instructions, found Cooper guilty of murder in the first degree and did not recommend leniency. The judge was obliged to sentence him to be electrocuted. After listening to the sentence, Cooper said, "Thank you."

POST TRIAL

There have been no executions in Massachusetts since 1947. After the conviction was affirmed by the Massachusetts Supreme Court, defense counsel, family and public petitioned the Governor to commute Cooper's sentence. Cooper, aware of the appeals on his behalf, wrote the Governor :

Now I do not ask for death in the form of punishment, but as mercy. Mercy in the guise of release from a life which is no longer honorable nor desirable. My wish is that you can put aside your moral regrets and do your duty, even as I have done mine.

In another letter to the Governor he wrote,

If I could but feel that I honestly regretted my actions, I would welcome the prospect of imprisonment and rehabilitation. However, while I do not lack the qualities of pity or compassion, I do not feel one iota of remorse for the crime I have committed. It is not the enormity of the crime itself, but the ease with which I justify it to myself that precludes the possibility of my ever returning to society again. Under these conditions, execution is the only logical conclusion.

At the Governor's request the Commissioner of Mental Health started a study of

the case to determine if Cooper was too sick to be executed. The State psychiatrists who conducted this examination had a theoretical orientation and personal training that was substantially similar to the defense psychiatrists. Five psychiatrists and one psychologist were involved in this post trial study of Cooper. Cooper was seen often by one or another of this group in the following 6 months. During this study period many reports were written to the Commissioner. One psychiatrist wrote :

Mr. Cooper is a pleasant, intelligent and responsive young man who shows no evidence of psychosis, nor does he show on first examination a sufficient degree of mental illness for me to recommend hospitalization (were he simply to walk into my office).

And further,

It is quite probable that once it is definite that he will not be executed the depression might deepen to the point of making a suicide attempt. . . . I do not think he should be killed, but at the moment at least, I cannot say that he is too "mentally ill" to be killed (whatever that means).

A State psychologist gave Cooper the standard psychological tests and concluded :

While on the surface this patient appears to be neurotic, his core problems and the defenses against them are psychotic in nature. His crime and his desire for destruction seem to be not a sudden eruption occurring in an otherwise normal person, but they seem to represent an attempted solution to a psychological conflict which had its beginnings in the early phases of childhood. Given his personality one might say that he had no choice but to act compulsively as he did.

The final report of this team to the Commissioner stated :

We find Mr. Cooper an interesting challenge in addition to being genuinely interested in him as a human being. Our impression is that he is quite treatable and might some day be a useful member of society. I hope we have the opportunity to continue working with him.

The Commissioner of Mental Health and the Commissioner of Correction each recommended commutation of sentence to life

imprisonment. When Cooper was told the Governor was about to approve their recommendations he hanged himself.

CONCLUSION

In the disposition of the case of this murderer the Law and the State turned to psychiatry for assistance for a variety of purposes. 1. The Court ordered a psychiatric examination to determine Cooper's competency to stand trial; 2. State-appointed psychiatrists conducted an examination under the Briggs Law to satisfy the State that Cooper was not suffering from any mental illness that affected his criminal responsibility; 3. Defense psychiatrists and a psychologist examined Cooper to prepare the only possible defense, "non-responsibility"; 4. The contradictory assessments of the competing psychiatrists were presented to judge and jury in the form of direct and cross-examination; 5. The jurymen on the basis of the judge's charge and their own sentiments and observations were meant to sift through the complexities and arrive at a decision; 6. The State, after conviction, turned once again to psychiatry to seek support for a decision to reverse the directive of the jury.

The result in this case would have been no different if the 9 psychiatrists and 3 psychologists had not been involved. Cooper would have been convicted and probably would have committed suicide.

If this case is at all typical of the current state of misunderstanding and confusion between law and psychiatry, as well as reflecting the dissension among psychiatrists, I seriously doubt the value of the psychiatrists' participation in any stage of the legal proceedings. I would not question the value of the psychiatrist to weed out the grossly disturbed offender in the pre-trial competency examination but why not let the law have its own archaic way with the rest.

In the Cooper case the State used one set of psychiatrists to prove that Cooper was "perfectly sane" and therefore "responsible" and the defense, other psychiatrists, to show that Cooper was sick and therefore "not responsible." The lay jury chose the testimony it could understand and which corresponded with their own sentiments and Cooper was convicted of a murder he ad-

mitted. The only flaw in this successful manipulation of psychiatric expertise was the State's ambivalence. Since there was much moral sentiment against capital punishment Cooper could not be executed and State proceeded to use its first team of psychiatrists to rationalize the decision not to execute.

The psychiatrists and psychologists used after trial had more in common professionally with the defense experts than they did with their colleagues who conducted the Briggs Law examination and testified at trial. If this group had done the pre-trial examinations and presented their testimony to the Court, Cooper might never have been convicted but rather received the treatment he obviously needed.

The Briggs Law examiners and the post-trial psychiatrists were all employees of the Department of Mental Health of the State. The defense experts were also paid by the State. Since Cooper had no money the State paid the defense psychiatrists \$350 each. The Briggs Law experts each received \$7 for their examination in addition to their regular salaries as state hospital superintendents.

While it is perhaps out of place for me as a lawyer to talk of rational Utopias I would like to suggest to you my alternative to some of the modish verbal formulas. I do not believe it is the particular technical phrasing of the test of criminal responsibility that is important. What is important is the feeling these words convey about the Court's attitude toward the offender. If the Durham test has any meaning it is the substitution of the feeling, "crime may be the result of sickness," for the feeling that, "crime is the result of conscious evil." If, however, psychiatrists feel that many crimes are motivated by mental illness the need for change is much greater than the call for a revised test of criminal responsibility. The explanation of a crime to a jury by a competent psychiatrist may be too complex both intellectually and emotionally for a jury to understand and act on. I suggest to you that a jury trial is not an appropriate forum for the presentation of psychiatric explanations of behavior. The function of a jury in a murder trial should be limited to a finding that an accused did or did not

commit the offense charged. Once guilt is established, a Sentencing Authority composed in part of psychiatrists and other professionally trained people, should, in the absence of capital punishment, decide what combination of treatment and/or punishment is appropriate to the individual offender.

Several months before his suicide Cooper wrote a poem which is not only particularly appropriate in expressing his feelings about himself, but also has some relevance to the procedure by which his case was handled.

Sunlight in patterns,
Rectangular shapes,
Covers my floor.

Moonlight imprisoned
Slantingly gapes
Through my door.

Night air comes creeping
Through the small windows
Cold, fresh and free ;

Willingly captured, like
Schools of small minnows,
Coming to me.

Starlight is filtered
Through dirty glass,
Soiling the sky.

And time is hollow
Never will pass,
Unless I die.

Where am I ?

REVIEW OF RAPID URINE TESTS FOR PHENOTHIAZINE AND RELATED DRUGS

FRED M. FORREST, M.D.,¹ IRENE S. FORREST, Ph.D., AND
AARON S. MASON, M.D.²

Since the late 1950's the phenothiazine and related drugs have been in large scale use in general medicine and particularly in psychiatry. Their versatility and manifold therapeutic effectiveness are almost universally acknowledged, while their action mechanism is still incompletely understood. Investigations on the metabolism of these compounds are still in progress and have yielded some significant results(8-12).

During our early investigations into the metabolic fate of phenothiazine compounds, we took a clue from some incidental observations, such as the obvious autoxidation of aqueous chlorpromazine solutions, rapidly turning brown when exposed to daylight, or the photosensitivity of patients on chlorpromazine therapy. Clearly, chlorpromazine had a very reactive nucleus, apt to produce a variety of oxidative derivatives. Assuming that some of the more reactive intermediates might be demonstrable in urine, a search for a simple, suitable reagent was started and resulted in the first rapid urine color test for chlorpromazine(1) (see chart, test I), whereby an acid solution of ferric chloride, mixed with urine, yielded a scale of purple colors proportionate to drug intake. A subsequent search of the literature showed that while there were few pertinent data for chlorpromazine, there was a vast body of literature for the parent compound, phenothiazine. The entire phenothiazine field—from the compound's synthesis in 1883 by Bernthsen(13), to its intensive recent investigation by Michaelis and co-workers(14-17), including all industrial and pharmacological applications over the last 70 years—has been comprehensively and competently reviewed in 1954 by Massie(18). Animal studies on metabolism and excretion of phenothiazine(19-22) showed that type and amount of drug metabolites varied from species to species, but that

the urines contained one or more partially oxidized or hydroxylated intermediary metabolites in all instances. The first basic metabolic data for chlorpromazine were reported by Salzman, Moran and Brodie(8). They identified, in human urine, the chemically unchanged, unoxidized chlorpromazine and its sulfoxide and described a procedure(9) for quantitative determination of both compounds, which account for 5 to 12% of the daily drug dose. This left a large balance unaccounted for. However, these two compounds, the beginning and the end of the human metabolic process, do not yield the intense purple color reactions obtained in the urines of patients with test I. Unoxidized chlorpromazine yields a pink color, while sulfoxide produces no color at all with this reagent.

Speculating that the partially oxidized, highly reactive intermediary drug metabolites might act as oxydo-reduction systems by means of which some of the therapeutic effects might be accomplished, we tried to duplicate the physiological metabolism of chlorpromazine *in vitro* by ultraviolet irradiation of aqueous drug solutions(23). While this did not produce any sulfoxide, it did indeed lead to the formation of an oxidative intermediate closely resembling the urinary metabolites responsible for the color tests.

While continuing to investigate the chemical nature of the elusive intermediates, the initial rapid urine color test for chlorpromazine was modified for the purpose of demonstrating other urinary phenothiazine drugs and to provide objective criteria for their intake(3-7). It is the purpose of this review to consolidate our findings and to reduce the number of the seven originally developed tests to an effective minimum with which general hospitals, mental institutions of all types, physicians in private practice, toxicology centers, mental hygiene and outpatient departments, *etc.* will be in a position to carry out an effective testing program

¹ V. A. Hospital, Palo Alto, Menlo Park Division, Calif.

² V. A. Hospital, Brockton, Mass.

with a small number of test solutions and corresponding color scales(1-5) (see chart).

SIGNIFICANCE OF TESTS

Thousands of chronic mental patients with many years of hospitalization have been rehabilitated through the use of drug therapy and discharged into the community(24-36). Many of these patients maintain this status successfully on maintenance drug regimens. It has become an established trend to provide aftercare for them in outpatient settings, in mental hygiene centers or by supervision of private physicians. The latter have frequently been reluctant to treat former mental patients, especially, if there was a known history of combative or other acting-out behavior. Most of these patients do not relapse under adequate medication, and hence objective criteria to evaluate drug intake are essential to the professional personnel dealing with the increasing number of patients on maintenance therapy in the community.

Within the mental hospital setting, it became obvious that the patients who were most benefited by systematic chemotherapy were frequently the most likely candidates to omit intake of their prescribed drugs. This was especially true of patients whose illness was characterized by catatonic, paranoid, depressive or negativistic symptomatology. As the nursing staffs on drug-controlled wards for formerly severely disturbed patients were drastically reduced, in many instances, it became a vital problem of ward safety to have objective criteria for actual drug ingestion.

Theoretical considerations also pressed in the same direction: Controlled studies on the therapeutic effects of various phenothiazine drugs have been undertaken or are now in progress, partly to settle controversies on the effect of drug therapy versus placebo or other therapeutic procedures. Whatever the goal, it seemed imperative to know rather than guess what was being evaluated in these instances(35). Spot checks as well as systematic testing of hospital populations showed that from 5 to 15% of patients in well-staffed hospitals, and more in under-staffed and not particularly drug-minded institutions, successfully "cheeked" their drugs(2, 35, 37, 45). This

is a superfluous drain on pharmaceutical budgets. For large hospital systems as e.g., the New York State Hospital organization or the Veterans Administration, which spend millions of dollars annually for phenothiazine drugs, the figures for annual waste may well amount to hundreds of thousands of dollars.

VALUE OF TESTS IN MEDICAL RECORDS

In some of our buildings for chronic mental patients the results of rapid urine color tests are made part of the medical records, since a patient's individual excretion factor on a stable drug dose is fairly constant. Thus, e.g., a patient on a daily maintenance dose of 400 mg. of drug, showing a urinary color intensity of "+ +" during his hospitalization, is expected to show the same excretion factor (+ +) on periodic return visits. This permits reliable evaluation of drug intake by patients on self-medication during trial visit or after discharge.

AVAILABLE TESTS AND DIRECTIONS FOR THEIR PERFORMANCE

In 4 years of intensive experience in testing for phenothiazine and related drugs in urine, we found the five tests condensed in the summary chart most useful in routine testing procedures. These tests are safe even in the hands of operators inexperienced in laboratory procedures and can be performed in any setting, from office desk to hospital ward. They involve the use of 4 different reagents. If only a minimum program is to be carried out, in which the emphasis is placed on establishing merely whether any phenothiazine drug is present, test V(5) alone will furnish this information, without yielding the more specific, semi-quantitative scales obtainable by tests I, II, and III(1-3) (see chart).

Tests I to V are performed by adding 1 ml. of reagent to 1 ml. of urine in a test tube, shaking gently, and reading promptly against the color chart. Test IV for imipramine(4) occasionally requires more than 1 ml. of reagent, if phenothiazine drugs are simultaneously present, and in test III for thioridazine, the maximum color may not develop before 20 seconds after mixing urine and reagent, especially at low doses.

We found it practical to dispense equal volumes of urine and test reagent by means of two graduated, rubber tipped medicine droppers, one for urine and one for the brown reagent bottle, the latter being mounted in a plastic screw top as a permanent tight closing stopper. Color charts should be placed against a light surface away from the window, since readings in transparent light would be too low.

URINE SPECIMENS TO BE USED

Almost any urine specimen may be used in the high and medium dosage ranges of the phenothiazine drugs, *i.e.*, the doses found effective in hospital psychiatry. To obtain consistent and reproducible results, it is preferable to perform all tests on morning urine specimens obtained on arising, before breakfast and medication. Normally, specimens of adequate concentration are obtained in this way. However, when 20 mg. of drug or less per day are given, this procedure may yield inadequate color reactions. Testing should then be repeated 1½ to 3 hours after drug intake, coinciding with peak excretion of drug.

EVALUATION OF TESTS

It should be emphasized that any color test reflects a momentary drug level, and that no distinction between a recently ingested low drug dose and a previously taken higher dose can be made. Neither is it possible to identify the specific drug ingested by performing a single test, since all phenothiazine derivatives react to some extent with the various test reagents. Positive identification of a specific phenothiazine compound can only be made by spectrophotometric or similarly specific procedures. Combinations of various phenothiazine drugs may be summarily evaluated by means of the universal test V.

STORAGE OF URINE SPECIMENS AND TEST REAGENTS

Urines may be stored for several weeks, refrigerated, with a few drops of toluene as preservative, without appreciable loss of drug. Glass containers should always be used, since plastic bottles or paper containers adsorb some of the drug content.

Prolonged storage is best achieved by freeze-drying of the specimens. This will preserve the original drug content and the original ratio of individual metabolites. Otherwise, prolonged storage will change both of these factors, decreasing total drug content and reducing some of the oxidative metabolites to unoxidized drug, probably due to bacterial action.

Reagents I through V are stored in dark glass bottles. They are stable without refrigeration and have a shelf life of a year or more. They can be readily and cheaply prepared by hospital pharmacies or laboratories, and should be properly labelled "poisonous" in view of their acid content.

LIMITATIONS OF THE INDIVIDUAL TESTS

Individual statistics on the occurrence of false negatives and positives are found in the original publications (1-7). In summary, it may be repeated that virtually *no false negatives* have been encountered. An occasional urine specimen may be very dilute after fluid intake of more than 2000 ml., or, the specific urinary drug level may initially be inadequate for satisfactory demonstration immediately after institution of low dosage therapy. In these cases specimens obtained 1½ to 3 hours after drug administration should be used. During this optimum period test V will permit detection of as little as 5 mg. of a single phenothiazine drug dose in persons without previous phenothiazine level. With regard to *false positives*, most of our experiences were previously reported (5, 38, 39). Some categories of false positives are common to tests III and V. Thus the urine of phenylketonurics, of persons with impaired liver function or on high doses of paraaminosalicylic acid or estrogen therapy, register false positives, of low color intensity. Tests I for chlorpromazine, II for promazine and mepazine, and IV for imipramine are not subject to the above false positives. Concerning potential false positives due to salicylic acid derivatives, *e.g.*, aspirin: Urines containing aspirin and its metabolites after intake of up to 30 grains, the highest dose seen, do not produce false positives with any of the tests. *In vitro* tests showed that 10 mg. acetylsalicylic acid added to 1 ml. of urine, corresponding approximately to an aspirin in-

take of 10 gm. or more, did not produce false positives.

Another source of interference with clear test colors was recently pointed out by Levine, Levine and Small(40). These authors consider urinary indican as one such agent producing false positives. However, the color development due to indican appears with considerable delay, whereas phenothiazine colors appear immediately and should be read within 10 seconds, as pointed out in the individual test directions. With strict observance of these directions no false positives due to indican are seen in tests I to V. Even the addition of 1 mg. of indican—a physiologically unlikely amount—to 1 ml. of urine already containing high amounts of indican, did not produce false positives in properly executed tests. Furthermore, a simple procedure, requiring only a few minutes, will eliminate indican by selective adsorption of this compound on an ion exchange resin(12). Adding 100 mg. Dowex AG 3-X 4 Anion Exchange Resin, 200 to 400 mesh, Chloride Form,³ to 3 ml. of urine in a test tube, shaking vigorously for one minute at room temperature and filtering, will selectively adsorb indican along with a number of other undesirable urine constituents, such as intense urine color *etc.*, with negligible loss in phenothiazine compounds. The tests are performed with 1 ml. of the clear filtrate, which usually appears lighter colored than the untreated specimen, and yield clearer color reactions, conforming more closely to those of the charts. The resin adsorption procedure is useful in connection with all tests, whenever maximum clarity of colors can not be otherwise achieved. While this procedure eliminates indican, aspirin, *etc.*, it does not eliminate false positives due to impaired liver function, conjugated estrogens, paraaminosalicylic acid, nor a number of endogenously produced hydroxylated metabolic compounds, as previously reported(5, 38, 39).

The more sensitive the individual tests are, the greater the potential sources of interference and false positives. Thus, the

extremely sensitive test VII(7) for the demonstration of piperazine-linked phenothiazine drugs, administered in the lowest daily dosage range, shows the highest percentage of false positives. With this test Heyman(41, 42) and Posner(43) found higher percentages of false positives in different hospital populations and controls respectively than seen in our hospital population. We therefore recommend the use of test V instead of VI(6) and VII(7) for detection of low dosage phenothiazine drugs (up to 100 mg. per day). For unequivocal results all color development appearing after the 10 second limit should be disregarded, and the resin adsorption should be used as an added safeguard in intensely colored urine specimens. The use of the most sensitive tests VI and VII should be reserved for such research projects as drug discontinuation studies, in which minimal amounts of drugs are to be demonstrated, and they might then also be suitably supplemented by test V. They remain useful due to the absence of false negatives, and to the formation of optimal colors for the type of drugs for which they were designed. Test colors obtained with these two reagents are slightly more intense and more stable than those of test V, but the incidence of false positives is considerably higher, if limited to the lowest level of the charts. Details of the composition of these sensitive reagents for triflupromazine (Vesprin)(6) and the various piperazine-linked phenothiazine derivatives(7), their storage, handling and color charts are contained in the original publications. In the special projects in which they may be used, the following precautions should be observed: Periodic testing of the reagents' potency against a specimen of known drug content should be performed. These tests are subject to the same categories of false positives as tests III and V, and color development due to indican may again be avoided by pretreatment of the urines with anion exchange resin. In specimens containing high amounts of indican which has not been filtered out, interfering color development (brown, olive, slate grey) distinguishable from the pink to purple phenothiazine colors, but appearing within 10 seconds, is seen.

OTHER RAPID URINE COLOR TESTS REPORTED

Sprogis and coworkers(44) reported a color test for chlorpromazine in 1957 calling for separate additions of concentrated hydrochloric acid and a critical, small volume of dilute sodium nitrite solution to urine. Being more cumbersome and producing less stable color development, it does not have the simplicity and ease of the simultaneously published test I (see table). Moreover, test I was consistently reported to be free of false positives(37, 38, 40), whereas Sprogis' test, due to its extreme acidity in this respect compares to test VII (7). Such acidity is unnecessary in the demonstration of urinary chlorpromazine.

A similar rapid urine color test based on two separate additions of nitric acid and sodium nitrite solution to urine was published by Neve(45) in 1958. He stressed the fact that some of the red to purple color reactions resulting in the presence of various medium to high dosage phenothiazine drugs may be so fleeting as to be almost imperceptible, and cautions against false positives due to a pink color reaction of urobilin with nitric acid. 10.7% of drug "cheekers" were detected by this method. Color reactions produced by this test are less stable than those obtainable with tests I, II, III and V. Furthermore, the sensitivity of universal test V is superior, thus allowing detection of smaller quantities of drug.

While these tests by Neve and Sprogis are correct and actually indicate what their authors report, there was a partially incorrect test reported by Fellman(46) in 1946. This author, using the standard test (5% ferric chloride solution) for the detection of phenylpyruvic acid in the urines of phenylketonurics, whereby green colors develop, detected a green color also in two urines of non-phenylketonurics. He attributed this green color development to chlorpromazine metabolites. This, however, undoubtedly is an erroneous interpretation: 5% ferric chloride solution, without an adequate amount of mineral acid, is unsuitable for specific demonstration of chlorpromazine or any other phenothiazine derived drug. In exceptional cases of extremely high drug intake, it is possible to produce a purple color even with

inadequately acid ferric chloride solutions, but the specificity for chlorpromazine would have to be verified by the addition of acid, *e.g.*, sulfuric acid, which would bleach color development due to aspirin, ketone bodies, phenylpyruvic acid, *etc.* but would enhance the chlorpromazine color. However, a chlorpromazine reaction with ferric chloride and acid would be purple, rather than green. The only instances in which green color reactions have been seen even with test I, were caused by the simultaneous presence of large amounts of reducing substances, *e.g.*, after intake of high potency multivitamins or ascorbic acid. In these cases, the normal purple color reaction could be readily restored by adding a few extra drops of test reagent I.

Moreover, phenylpyruvic acid as well as other ketonic and aldehydic substances form addition compounds with the phenothiazine drugs and their metabolites on which we will report later(12). In the presence of such addition compounds, the characteristic color reactions of the phenothiazine drugs are modified. While these normally appear almost instantaneously, they are considerably delayed in the urine of phenylketonurics.

The second reagent for urinary chlorpromazine reported in Fellman's article(46) is a mixture of sulfanilic and hydrochloric acids to be added to urine, to be followed by a subsequent addition of sodium nitrite, resulting in the appearance of a purple color. This test is valid, if not very practical.

Fellman's erroneous interpretation of the above-mentioned green color reaction observed in urine containing chlorpromazine with 5% ferric chloride solution, gave rise to two additional, outright misleading reports in 1959: Vesell(47) reported 10% ferric chloride in 1% hydrochloric acid as a suitable reagent for the detection of small amounts of prochlorperazine (Compazine) in the urine of a child having ingested a total of 80 mg. of the drug over a period of four days, and showing alarming side-effects characteristic of piperazine-linked phenothiazine drugs. We could not confirm his findings in the urines of patients containing many times the amount of prochlorperazine, nor did his reagent prove suitable for the detection of other more readily demons-

trable phenothiazine drugs in amounts below 400 mg. per day. Our comments(48) were reported promptly, since reliance on an incorrect test for differential diagnosis between dystonia due to phenothiazine toxicity and muscle spasms due to tetanus would be a hazardous practice.

Another simultaneous and incorrect report was published by Nellhaus(49). He added "Phenistix," a commercial reagent strip, as a potential reagent replacing 10% ferric chloride solution. Phenistix is equally unsuitable for the detection of phenothiazine derivatives, but it yields a good scale of green colors for urinary phenylpyruvic acid, and a scale of pink to purple colors with salicylic acid derivatives, *e.g.*, aspirin or paraaminosalicylic acid.

Nellhaus also states that our tests I and II for chlorpromazine and analogous drugs (see chart) were "popularizations" of Fellman's test. Since we found Fellman's 5% ferric chloride reagent equally unsuitable for the demonstration of urinary phenothiazine drugs, we would like to correct this error along with some others contained in this short communication: A red color reaction between the unsubstituted *phenothiazine* and *strongly acid ferric chloride* was first accurately described by Bernthsen(13), the discoverer of phenothiazine, in 1883. We noted that the intermediary oxidative metabolites of phenothiazine derived drugs yield intensely colored, mostly purple reactions, directly in the urine, with properly formulated, adequately acid ferric chloride solutions. Any reddish to purple color shades obtained in urines by the addition of excessively concentrated and hence intensely yellow 5 or 10% ferric chloride solutions *without* addition of adequate amounts of mineral acid, do not indicate *phenothiazine* derivatives, but as previously mentioned, *e.g.*, aspirin and its metabolites, or "ketone bodies"(50).

To sum up the chemical prerequisites for direct demonstration of urinary phenothiazine derivatives, an overall acidity of pH 1 or less, according to quantity and type of drug present, must prevail in the mixture of urine and reagent. Only under these circumstances can rapid urine color tests produce specific phenothiazine color reactions. In some instances, these may be obtained with acids alone, in others with acids containing small amounts of nitrite or heavy metal ions, for instance ferric ions.

SOME CHEMICAL DATA ON URINARY PHENOTHIAZINE DRUGS

Among the various phenothiazine drugs, the metabolic fate of chlorpromazine has been most thoroughly investigated: apart from the unoxidized drug and its sulfoxide detected by Salzman and Brodie(8, 9), other metabolites, partly in free form and partly as glucuronic acid conjugates, with oxidative changes in the nucleus and demethylation in the side-chain, have recently been reported(51-54).

According to our own data(12, 55) concerning chlorpromazine, the average daily urinary excretion during continuous drug administration, approximates one-half of the daily drug intake, and a lesser proportion in single drug doses. The balance is apparently excreted in the feces(57-60), with some storage in various body tissues being obvious from data on prolonged excretion after drug discontinuation(10-11). Of the amount of drug contained in urine only about 20% are in the form of the solvent extractable metabolites, whereas the balance of 80% of urinary drug content was found to be in the form of polar, intermediary oxidative metabolites comprising various types of hydroxylated derivatives(11, 12, 55). Both the absolute amounts of individual drug metabolites and their ratio were found to vary substantially from drug to drug, and to a lesser extent for different patients on the same drug therapy. Simple new, quantitative methods for determining total drug content and ratio of individual metabolites, some of which contain free radicals, have been devised and are being prepared for publication(12, 55).

In this connection it might be mentioned that in the administration of phenothiazine drugs, no essential differences in therapeutic efficacy and urine color tests were noted for intramuscular and oral doses of chlorpromazine (tablets or syrup) in the same individual, while spansule type medication was repeatedly found to require a 30% increase in dose to obtain the previous clinical effect of tablets and urinary drug level according to test I.

While investigations on phenothiazine metabolism and excretion are likely to continue in many laboratories for some time to come, and will extend to newly synthesized

drugs, the above data might in the meantime be helpful to investigators in this field. With regard to rapid urine color testing, the available reagents and the individual color scales of the chart, as summarized here, are fairly comprehensive and adaptable to the various categories of phenothiazine and imipramine drugs to be expected.

THE CURRENT STATUS OF PSYCHIATRY IN THE UNITED KINGDOM

HENRY P. LAUGHLIN, M.D.¹

In 1957 and in 1960 I served as the Delegate of the American Psychiatric Association to the Royal Medico-Psychological Association of Great Britain(1, 2). This article is a summary of the report which I prepared for the APA Council following my latest trip.

In the 3-year interval between my two official visits a number of developments, present and pending, are worthy of our attention. The report of the Royal Commission on the Law Relating to Mental Illness and Mental Deficiency was rendered in 1957. The new Mental Health Act became official in 1959 and operative in the fall of 1960. Since 1957 there has been a significant and somewhat surprising growth of voluntary health insurance plans.

The National Health Service has made progress and, despite the foregoing, is a firmly entrenched socio-political fact in the United Kingdom. The R.M.P.A. continues to flourish. There is more private practice of medicine generally and of psychiatry. I shall comment briefly on these and certain other possible areas of interest.

1. THE ROYAL COMMISSION REPORT

In 1957, following intensive study of the exceedingly complex legislative, social, and medical aspects of mental health areas, this multidisciplinary group (including psychiatrists T. P. Rees and D. H. H. Thomas) produced a highly significant report. The recommendations of this Commission provided the basis for revising a great deal of existing legislation and procedure.

2. THE NEW MENTAL HEALTH ACT

This Act is the legislative consequence of the preceding Commission Report. Described more fully in an earlier article in this Journal by Dr. W. S. Maclay(3), it is a fundamental revision of English mental health law, replacing or partly replacing 52 prior Acts. The consequences in the manage-

ment, disposition and treatment of the more serious mentally sick patients are substantial.

The new Act has widespread public and professional support and reflects the changing public attitudes in the United Kingdom concerning the field of psychiatry. It should produce a number of constructive changes, including: 1. Simplification of commitment and other procedures; 2. A further shift of psychiatric services into the community; 3. The local authority to have more of the responsibility in patient management, *etc.*, in place of the mental hospital; 4. A possible growth of psychiatric units in general hospitals; 5. Generally more understanding and humane attitudes toward mental illness; 6. Voluntary admissions and minimal use of compulsory powers; 7. The establishment of a Mental Health Tribunal for patient appeals.

3. THE NATIONAL HEALTH SERVICE

The National Health Service has been in operation since July 5, 1948 and has become an accepted establishment. The total impact upon medical practice and patient care has been tremendous. To the American observer the effects have not been all good by any means, neither have they been all bad.

In general, British psychiatrists seemed less inclined to be critical of the N.H.S. currently than upon prior visits. This may be due to a number of factors, including certain improvements in N.H.S. operation, the new Mental Health Act, certain salary increases and the passage of time. In recent years there has been steady progress in the staffing of hospitals generally, including the psychiatric hospitals. Although the great majority of psychiatrists work in the hospitals, there is an increasing amount of community work underway.

The N.H.S. Consultant Psychiatrist: Of the estimated 2100-2400 psychiatrists in the U. K., which comprises England, Wales, Scotland and Northern Ireland, over 700 are N.H.S. consultants, full or part-time. Part-time status (giving no more than

THE ROYAL MEDICO-PSYCHOLOGICAL ASSOCIATION
One Hundred and Twentieth Annual Meetings at Coulsden, Surrey, and London, England.

..... Taken at Cane Hill Hospital on July 13, 1960 by Dr. Robert W. Armstrong of Oxford and Bournemouth, R.M.P.A. Past-President.

Dr. A. B. Monro of Epsom, General Secretary of the Royal Medico-Psychological Association; Dr. Alexander Walk of Coulsden, R.M.P.A. President; Dr. Henry P. Laughlin of Washington, Delegate of the American Psychiatric Association; Dr. Angus MacNiven of Glasgow, Scotland, Immediate Past-President of the R.M.P.A.; and Dr. William McCartan of Co. Down, N. Ireland, R.M.P.A. President-Elect.

9/11ths of one's time to N.H.S.), is sought by some psychiatrists in order to allow some private practice, and for tax deduction of certain car and utility expenses. As we consider N.H.S. salary scales we shall see that adding to one's income leads to an increasing surtax.

Salary Scales and Tax Rates: Salary arrangements for N.H.S. consultants in the various specialties are similar. The beginning physician receives an initial base salary of \$6400. Over a 10-year period this can gradually rise to his maximum base pay of \$10,900. All figures are approximate conversions into dollars from pounds sterling. They are from the new and improved N.H.S. pay scales which became effective toward the close of 1960.

"Award monies" are granted in addition to the basic salary. There are four levels: "A"=\$7700 which is granted to some 4% of all consultants; "B"=\$3600 which 10% receive; and "C"=\$2100 received by approximately 30% of the consultants. Exactly 100 super "A" awards, amounting to \$8400 each, are available among all N.H.S. physicians.

Taxes take a substantial bite from earnings and increase rapidly as one's salary rises. As an example, a married physician with two children, having a total N.H.S. income of \$9400, pays \$2240 standard income tax, plus \$280 surtax, leaving him a net income of \$6880.

4. GROWTH OF VOLUNTARY HEALTH INSURANCE

It was most interesting to learn of the rather remarkable growth of voluntary health insurance plans. From a negligible total of persons included as recently as 1956, various plans in force today already cover an estimated 2½–3 million people, some 1/15th of the total population.

Over this same period there has been a noticeable rise in the national economy. This appears to be reflected in the health interests and needs of people generally. Accordingly they may seek to supplement or replace N.H.S. services. Private care can be secured. Commercial health insurance can be purchased. Many variations of coverage are offered. Some improve N.H.S. facilities; e.g., a private hospital room in the event of illness. Some provide complete

coverage outside of N.H.S. Many plans include psychiatric services.

5. INCREASE IN PRIVATE PRACTICE

Economic growth has also helped encourage the private practice of medicine. Psychiatrists are among those who are seeing more private patients. More are becoming part-time N.H.S. consultants, allowing them also to see patients on a private, fee basis. Some regard the maintenance of an N.H.S. affiliation as necessary, since hospital and other staff positions are under its aegis and such an appointment may be a prerequisite to receiving referrals.

There is more reserve concerning fees in England than in America. A few years ago I was a member of a special APA Committee which had little difficulty securing specific data concerning their fees and income from several hundred colleagues. I believe this would present considerably more difficulty in the U. K. The best consensus concerning private fees would suggest a per session charge of 5 to 7 guineas (\$15 to \$21) might be made by the Harley Street psychiatrist.

6. THE ROYAL MEDICO-PSYCHOLOGICAL ASSOCIATION

The RMPA is the oldest association of psychiatrists in the world. Founded in 1841, through the initiative of Dr. Samuel Hitch of the Gloucester Asylum, it antedates the APA by 3 years. It has likewise gone through several name changes, and has gradually grown to its current membership of 1800. The present name and royal charter date from 1926. About 100 new members are elected annually.

Prior to the turn of this century, five major area divisions were established, three in England and Wales, and one each in Scotland and Ireland. Each holds scientific sessions, and those of Scotland and Ireland also deal directly with their government departments.

In 1946 the formation of sections became possible and four have been formed: 1. Child psychiatry; 2. Mental deficiency; 3. Psychotherapy and social psychiatry; 4. Research and clinical. Sections² meet dur-

² An RMPA member may belong to one, all or none. He is also free to attend any section meeting.

ing general meetings, hold their own programs and elect their own officers. The *Journal of Mental Science*, published since 1853 (the *American Journal of Psychiatry* was founded in 1844) is the official publication of the Association.

Meetings are marked by a cordial atmosphere and I could hardly have received a friendlier reception than upon the occasions I have been privileged to meet with my U. K. colleagues. The accompanying photograph pictures the present and upcoming leaders of the R.M.P.A. and continues this group without interruption from those included in the previous photograph in the March 1960 issue of the *American Journal of Psychiatry*.

7. OTHER NATIONAL PSYCHIATRIC GROUPS

The Psychologic Medicine Division of the British Medical Association includes over 600 members, most of whom are also members of the RMPA. This group represents

the psychiatric viewpoint within the B.M.A.

The British Psycho-Analytical Society was founded in 1913, becoming known by this name in 1919. The latest report lists 101 members and 123 associate members. The headquarters address is 63 New Cavendish Street, London, W.1.

A Group for the Expression of Views of Clinical Psychiatrists, also known as "The Oedipal Group" has some 150 members. There are also smaller Adlerian and Jungian societies, with headquarters as follows: The Adlerian Society of Great Britain, 42 Fortune Green Road, London, N.W. 6, and the Society of Analytical Psychology, 30 Devonshire Place, London, W.1.

THE RESPONSE OF SEVERELY ILL CHRONIC SCHIZOPHRENIC PATIENTS TO SOCIAL STIMULATION¹

J. K. WING, M.D., PH.D., D.P.M.,² AND R. K. FREUDENBERG, M.D., D.P.M.³

A number of controlled studies have been made in which occupational therapy for chronic schizophrenic patients has been contrasted with drug treatment. In these studies, occupational therapy has been prescribed in much the same way as a drug, and improvement in behaviour has been described in terms of a global rating or score (4, 6). It has not been possible to gain from these experiments—because of the difficulties in methodology—any suggestion as to principles which should underlie the rational prescription of social treatments. Controlled trials specifically testing these measures (particularly group psychotherapy) have been carried out very infrequently, and those which have been published have not yielded very positive results. One very common finding, however, has been that deterioration occurs in the control group which has not received the treatment, even where no improvement has occurred in the experimental group (1, 5, 7, 8, 13, 14).

Studies by members of the Medical Research Council Social Psychiatry Research Unit, using output in an industrial workshop as an objective measure of progress, have seemed to confirm the lack of effect of social measures. Output improves with practice, but additional incentives such as money, goal-setting, encouragement, and routine psychiatric interviews, appear to

have little incentive effect. In paranoid patients, output may even decrease (10, 12). This contrasts strongly with the marked effects of such incentives in imbeciles (2, 9, 11). A characteristic of the learning curve in the studies of output of schizophrenics has been the slow and linear improvement due to practice which contrasts with the more usual negatively accelerated form seen in normal people and imbeciles.

It has not proved possible in any of the studies so far published to lay down such rigorous conditions of selection, matching and procedure that the experiments could readily be repeated. The results of each paper, and the interpretations of the authors, are therefore difficult to compare. There certainly remains a strong clinical impression that the more stimulation (sensory and social) that a withdrawn chronic schizophrenic patient receives, the more activity he will show, and the better able the staff will be to turn this activity to good account. The studies mentioned above show that there is no question of a clinical cure, but they leave open the question of whether there may be improvement in certain specific aspects of behaviour. The difficulty lies in devising objective measurements of a wide variety of aspects of behaviour, and in controlling the many variables, other than those under investigation, which may alter the patients' responses in an unpredictable way.

The present experiment was a pilot project designed to discover whether there were any obvious changes in output, workshop behaviour, and ward behaviour, in a small group of severely ill long-hospitalized schizophrenics, when conditions of supervision were experimentally varied. The hypothesis was put forward that such patients respond to social stimulation, but relapse when the stimulation is discontinued. The social stimulation given was considerably more intensive, and more dependent upon the judgement of the supervisor, than in O'Connor's experiments.

¹ An experiment of this kind can only be made if the active collaboration of a large number of staff can be secured. We were particularly fortunate in this respect and would like to acknowledge our debt to Staff Nurse Alison, Dr. D. Bennett (consultant in charge of the rehabilitation programme), Staff Nurse Carr, Dr. A. Catterson (ward doctor), Miss A. Constable (senior Occupational Therapist), Charge Nurse Randall, Miss M. Smith (Matron), Mr. O. M. Hughes (Chief Male Nurse), and the staff of the Resocialisation Unit.

² Institute of Psychiatry, Maudsley Hospital, London S.E. 5, England.

³ Physician Superintendent, Netherne Hospital, Coulsdon Surrey, England.

SELECTION OF PATIENTS

Only severely-ill male schizophrenic patients who had been in hospital for more than 2 years and were under 60 years of age were considered for selection. Two special hospital villas, under the personal supervision of the clinician (R.K.F.), had been organised to provide intensive social treatment for 70 severely handicapped schizophrenic men and women. Of the 32 men, 1 was excluded because of a diagnosis of "simple" schizophrenia, 1 because, at the time, his symptoms were of moderate severity only, and 3 because they were already engaged in higher level industrial work and would have lost a substantial amount of pay if they had taken part. The drug treatment of the remaining patients was discontinued. Within the subsequent 3 weeks, 3 patients showed marked disturbance of behaviour which might have been due to the cessation of medication, and drug treatment was therefore resumed in these cases. The remaining 24 patients began work in the experimental workshops 2 weeks after drugs had been stopped. A further 2 patients were excluded after 8 weeks because they developed very high outputs. They were transferred to higher level work and their output has not been included in the following results. The experiment was therefore concerned with 22 severely ill male schizophrenics, all of whom showed severe flattening of affect, and either very severe poverty of speech or very severe incoherence of speech, so that normal conversation was extremely difficult or impossible. No patients had coherently expressed delusions as a predominant symptom.

SOCIAL CONDITIONS IN THE WARD

The social and administrative routines in the Resocialisation Unit where all the patients lived were of a high standard, although it was what used to be known as the "deteriorated" ward. A description of these social circumstances is included because it is thought that, unless demonstration of a minimum standard can be made, it is very difficult to interpret any changes which occur after the introduction of an experimental treatment. The two open villas, one for male and one for female patients, were administered as one unit, and the patients mixed in

all their activities during the daytime. Male and female staff shared similar duties and there was a high staff-patient ratio (1:8.75). There were weekly meetings of small groups of patients with a nurse and another staff member, and regular joint staff conferences. There was also a weekly ward meeting of all staff and patients. The usual daily routine was encouraged, and the patients left the ward to do subcontracted industrial work in the occupational therapy department from 9:30-12, and 2-4:30 every day. Various leisure time activities were organised, and patients also helped with domestic activities outside working hours. Detailed attention was paid to the re-education of personal habits of cleanliness, neatness and good manners. A deliberate effort had been made to create a unit that was not only a therapeutic milieu for the patients but also attractive for staff to work in.

THE EXPERIMENTAL WORKSHOPS

Two rooms were used as experimental workshops. One was larger and lighter than the other. They were connected by a communicating door which remained open throughout, and there was considerable movement between them. Eleven patients worked at two tables in each of the rooms. Two 2-hour trials were conducted daily, roughly from 9:45 to 11:45 a.m., and from 2:15 to 4:15 p.m. Times of beginning and ending work were noted and all output corrected to a full 2-hour period. Wednesday afternoon was worked by most patients but 3 or 4 patients regularly had visitors on this day, and others occasionally did, so that this trial was omitted from the calculations. There was no Saturday working. An occasional day was missed because of a public holiday or a coach outing.

The work consisted of tucking in a small triangular flap on each side of a cardboard sleeve, so that the glass globe of an electric light bulb could rest on the flaps, inside the sleeve, with the metal part of the bulb projecting through. The sleeves came in bundles of 50, each secured by an elastic band. The supervisor was allowed to keep a supply of bundles in front of each patient, if he did not supply himself from the carton, and to remove the elastic band if the patient did

not do this himself. The supervisor also checked that there were 50 in a completed bundle, and put on an elastic band if the patient did not do so. No actual sleeve folding work was done for the patient, except during two initial training sessions which were not scored. A standard method of folding in the flaps (one at a time) was taught, and all patients but one used this method throughout. The other patient occasionally adopted a two-handed method which was considerably faster. It is well known to industrialists that changes in method of working can produce increases in output compared with which other changes in conditions (*e.g.*, introduction of bonus payments, *etc.*) may have only marginal effects. It is thought that conditions in this respect were standard throughout the experiment.

An individual's score for any one 2-hour trial consisted of the number of cardboard sleeves he had completed—usually in multiples of 50. One patient, whose mental state was characterised mainly by coherently expressed delusions, worked very rapidly and efficiently, and his output over 8 weeks took the form of a typical learning curve except

that the flattening noted by O'Connor was still evident (Figure 1). He and another patient, as mentioned earlier, worked so fast that they had to be omitted from the experiment after 8 weeks. His output per trial at this point was about 3,000, and his pay (at 1/3d per 1,000) reached 35/- a week. Figure 1 gives some estimate of the maximum possible output for chronic schizophrenic patients under these conditions. The average pay, over the course of the experiment, omitting these two highest scorers, was 4/- a week.

Unfortunately, this most suitable work was obtained on a limited subcontract which could not be renewed, and it did not last for the whole of the experiment, in spite of the exclusion of the two highest scorers. During trials 70-82, 1-hour sessions were adopted. The remaining hour was occupied with coil-stripping—a much less skilled form of work with very low pay. However, a 2-hour trial was compared with the 1-hour trial immediately preceding and following it, and it was found that no significant distortion would be introduced if the outputs of the 1-hour trials were doubled to make them comparable with the rest.

A confirmatory study using a more complicated form of work—box nesting—was undertaken. Two pieces of cardboard 8" by 2½" with 3 slots in each, were held parallel to each other, in the left hand, and 3 cross-pieces, 6" by 2½", each with 2 slots, fitted across them to form a nest of 12 "boxes." Three initial training sessions were not scored.

THE MEASUREMENT OF WARD AND WORKSHOP BEHAVIOUR

During trials 1-16 the investigator (J.K.W.) and the ward doctor (A.C.) worked out a system of time-sampling workshop behaviour which was applied during the remaining trials. Four scales were constructed (see Appendix A) for rating immobility of posture, mannerisms, laughing and talking to self, and restlessness. Observations were made by the investigator or the ward doctor on 4 mornings each week. The patients at each table were observed for 15 minutes with particular reference to the items of behaviour most relevant to the rating scales, and observations were re-

FIGURE 1

Output Per 2-Hour Trial of Highly Motivated Chronic Schizophrenic Patient Whose Leading Symptom Was Coherently Expressed Delusions

corded in the form of brief descriptive notes. The investigator later rated these notes on the scales of Appendix A.

The notes made by the investigator during trials 37 and 40, and by the ward doctor during trials 35 and 38 (*i.e.*, 4 consecutive mornings during one week) were typed out on slips of paper. Identifying material was removed and the slips placed in random order. They were then rated, on the 4 scales, by an independent rater. Correlation coefficients were calculated, for 3 of the scales, between the 4 sets of ratings made at the time, and the 4 sets of ratings made by the independent rater subsequently. Too few patients were noted as showing mannerisms during the 4 periods of observation to make parametric statistics applicable—there was practically complete agreement on this point. The mean coefficients for the other 3 scales were 0.86, 0.96, and 0.62.

A simple 12-item ward behaviour rating scale was completed by the ward charge nurse at the end of each week of the experiment, except for 3 weeks when he was on holiday. Two scores were derived from this schedule. The first score ("Social Withdrawal") was composed of ratings on 8 items—social withdrawal, disinterest in leisure activities, lack of conversation, slowness, underactivity, poor personal hygiene, poor mealtime behaviour, poor personal appearance—which all correlated together. The second score, "Socially Embarrassing Behaviour," was composed of ratings on 4 items—overactivity, laughing and talking to self, posturing and mannerisms, threats or violent behaviour—which also correlated together. The two scores were not intercorrelated. There was satisfactory reliability as between raters.

PRELIMINARY MATCHING AND EXPERIMENTATION

The 22 patients were divided into two equal groups, one in each workshop. The two groups changed rooms at the beginning of each week throughout the experiment because of the pleasanter working conditions in the larger room. There was no evidence that either room stimulated greater output than the other. A male and a female staff nurse were chosen as supervisors and, during the preliminary 2 weeks, they alternated

daily between workshops, so that all patients were supervised as much by one as by the other. At the end of 2 weeks it was possible to look for the effect of each supervisor on output, but no differential effect could be found.

The output during these 2 weeks could therefore be used to match two groups of 11 patients. This was done by obtaining mean scores for trials 1-7 (during the first week in the workshops) and allocating alternate patients, in rank order, to one of two groups. After two small adjustments, there was no significant difference between the two groups, and they were also adequately matched for trials 8-16. In fact, no further adjustment could be made which would improve the existing equivalence of the two groups in respect of age, length of stay in hospital, and ward behaviour scores. The values are shown in Table 1. A rating of predominant mental symptoms had been made by the investigator before the beginning of the experiment. All patients were severely ill and all showed symptoms which markedly interfered with their conversation on neutral topics. Nine patients in each group showed severe blunting of affect and poverty of speech, the remaining patients showed severe incoherence of speech. The scales used for rating the patients on mental state will be described elsewhere. The group allocated to the female supervisor was labelled Group A. The other group was called Group B.

CONDITIONS OF WORKSHOP SUPERVISION

Following the preliminary two weeks in the workshop, each group was allocated its own supervisor. The supervisors were recently qualified staff nurses chosen by the clinician because they were representative of a good average standard of nurse in the hospital, and because they could be released from other duties for the period of the experiment. It was thought that any results they obtained could be reproduced by the majority of their colleagues.

Two conditions of supervision were defined. During "passive" supervision, the supervisors were instructed to carry out the administrative procedure described earlier, so that patients always had work in front of them ready to do. Otherwise they were to

concern themselves only with collecting work, checking it and entering it in the record book. They could correct mistakes but make no other comment on the work. They could deal with any incident which required intervention in any manner that seemed best to them. The behaviour of the supervisors under these conditions was observed during a period of 15 minutes following the investigator's time-sampling of patients' behaviour. In general there was silence during these sessions unless the supervisor wanted help in stacking the work, and the passive conditions of supervision were adhered to very closely.

Simple written instructions for active supervision were given to the supervisors. Patients who were already working well were to be praised and encouraged, and told what their output was and what their previous best had been. They were also reminded of the money value of their work. Patients who worked intermittently were to be encouraged particularly during periods when they stopped work. Patients who did not work at all were to receive special demonstration and attention. In no case was more than a few minutes to be spent with any patient, and whenever there was any sign of irritation the supervisor was to desist. The supervisors were to adopt the method of approach and choice of words which seemed to them best for each individual. In no circumstances was any work to be done for the patient. Time-sampling during the periods of active supervision showed that the supervisors kept closely to their instructions, in that there was little other verbal comment apart from praise, encouragement and goal-setting.

An initial period of 4 weeks (trials 1-32)

was allowed to overcome practice effects. Since, at the end of this time output was still increasing, it was decided to introduce active supervision for group B but not for group A. After a fortnight of these conditions (trials 33-50), passive supervision was resumed in both groups for a further 2 weeks (trials 51-69). Active conditions were then reintroduced for both groups and continued until the contract had been worked out (trials 70-82). This design allowed for a comprehensive test of the hypothesis that additional social stimulation increases output in this type of patient. A further check was provided by the subsequent introduction of more complex work, first under passive conditions of supervision (trials 83-86), then active (trials 87-91), and finally passive again (trials 92-94). Between trials 82 and 83, while the new work had not come in, the patients worked for 2 weeks at coil-stripping, under passive conditions of supervision.

RESULTS

1. *Output*: The mean scores per individual for each 2-hour trial are shown, separately for Groups A and B, in Figure 2. The peak output for any individual was 1,600 sleeves (on the 74th trial). This was only 50% of the peak output (on the 56th trial) of a highly motivated patient who demonstrated little handicap (Figure 1). The general level of functioning was thus extremely low. During trials 1-16 (before the groups had been finally chosen and supervisors allocated) there was no overall tendency towards improvement in output. However, when the mean scores are seen in conjunction with the figures for trials 17-32, during the subsequent 2 weeks, a

TABLE 1
Preliminary Matching of Two Groups of Patients
(Age, length of stay, behaviour, output)

	GROUP A		GROUP B	
	MEAN	RANGE	MEAN	RANGE
Age (years)	41.0	25-55	38.6	28-54
Length of stay (years)	14.3	6-30	14.0	6-30

Socially embarrassing behaviour	2.5	1-5	3.0	1-6
Group output per trial:				
Trials 1-7	2120	1550-2500	2528	1700-3500
Trials 8-16	2172	1500-3050	2711	2300-3200

FIGURE 2
Mean Output Per 2-Hour Trial for Individuals in Groups A and B

trend does become apparent. This can reasonably be attributed to a practice effect. When active supervision is introduced for Group B (trial 33) there is an immediate increment in mean score, but no further increase thereafter. A sudden increase is also seen in Group A but there follows a marked drop in output throughout this period. When passive conditions of supervision are resumed (trial 51) the output in Group B drops sharply, while that in Group A increases equally sharply. The output then remains stable until the reintroduction of active supervision, this time in both groups (trial 70). The immediate increase in output in Group A is of the same order as the earlier increase in Group B. There is an even more marked increase in output in Group B. A natural experiment was conducted when the male supervisor fell ill suddenly. During trials 80, 81 and 82, 3 different student nurses deputised for him and endeavoured to keep up the active supervision. The output dropped markedly, while output in Group A was not affected. The output of more complicated work (trials 83-94) is not shown in Figure 2. There is a smaller proportionate effect of active supervision, but the rise in output when active conditions are introduced, and the fall when they are terminated, is again striking.

The output figures for the two groups are summarised in Table 2. Mean output scores

were derived for each group, representing the output over blocks of trials during which the experimental conditions did not vary.

* Active conditions of supervision.

The data in Figure 2 and Table 2 seem to indicate clearly that there is a relationship between social stimulation and output. The fall in output, which occurs consistently whenever the extra stimulation is removed, is particularly striking, because it cannot be accounted for in terms of practice effects. However, it is clearly important to allow for any overall trend due to a practice effect before investigating the significance of the changes induced by varying the type of supervision. Seven patients in Group A and 4 patients in Group B increased in mean score from Block 1 to Block 2. These patients improved from a mean of 391.7 during the first period to a mean of 558.8 during the second. The remaining 11 patients actually declined from a mean of 39.9 to a mean of 20.3. There is a higher than expected correlation between the mean score per individual for Block 1 and the mean increment or decrement in Block 2 ($r = +0.84$, $p < .001$). Apart from one case (ranked 13 on initial output) those patients who increased in score from Block 1 to Block 2 were the highest initial scorers, while those who decreased were the lowest initial scorers. (Four patients who did no work in either period were included in the latter group.) However, although the 11 high initial scorers accounted for 91% of the total output in Block 1, and 95% in Block 5 (both under passive conditions of supervision), they accounted for only 73% of the total

output in Block 6 (active conditions). It is clear therefore that the 11 low initial scorers were responsible for a disproportionate amount of the increase in output when active conditions of supervision were introduced.

Thus the 11 patients who initially had a high output contributed most of the practice effect, while the remaining 11 patients were responsible for a substantial proportion of the increase in motivation. The two groups must therefore be analysed separately.

So far as the 11 who showed a marked practice effect are concerned, a maximum point was selected for each one, defined as the first trial following which there were 15 trials with no further increase in output. Slopes and levels were calculated for these 15 trials together with any other trials to the end of the current block. An extrapolation from these slopes and levels allowed the calculation of an expected mean score during Block 5, assuming that the trend had continued without interruption. In 2 cases the calculated level was higher than the observed level and the increase during Block 6 could be explained on the basis of a continuation of an earlier trend. The remaining 9 individuals showed an increase, from Block 5 to Block 6, which could not be so explained. The correlated *t*-test showed a significant increase for these 9 patients ($t=5.63$, $p<.001$).

Turning to the analysis of the scores of the remaining 11 patients, there is no practice effect to allow for, and any increase during periods of active supervision can be provisionally attributed to the effect of increased motivation. A 2×6 analysis of variance of the scores was carried out and showed very highly significant effects between blocks of trials, between the two groups, and also a very highly significant interaction. Subsequent *t*-tests showed no significant difference between any of the blocks of trials for the 4 patients in Group A. The 7 patients in Group B showed a significant increase from Block 2 to Block 3 ($t=2.34$, $p<.05$), a significant decrease in Block 4 ($t=2.50$, $p<.02$) and a further significant increase in Block 6 ($t=7.54$, $p=.001$). This is confirmed by examination

of the output data for each individual patient.

Thus 9 out of 11 initially high scorers, and 7 out of 11 initially low scorers, showed a significant response to active supervision, irrespective of practice effects.

When the more complicated work was introduced, there was still a significant increase in output under active (Block 8) compared with passive (Block 7) conditions of supervision ($t=2.85$, $p<.01$). More important, because practice effects are allowed for, there was a significant decrease on reversion to passive conditions ($t=2.33$, $p<.05$).

Throughout the experiment, there was no evidence that sex of supervisor had any influence on the results. There was the usual wide variation in output from trial to trial which is characteristic of schizophrenic patients. Apart from a fairly constant rise in output on Friday afternoons (pay day) and fall on Monday mornings, which these patients shared with their colleagues in open industry, no systematic interpretation of the diurnal variations can be offered.

2. Time-sampling of workshop behaviour: The workshop behaviour ratings made during each of 5 consecutive fortnightly periods were summed, giving total scores for each group of patients representing their behaviour during that fortnight. The first 4 periods corresponded to trials 17-32, 33-50, 51-69 and 70-82 respectively. The fifth period was the intermediate fortnight between trials 82 and 83, during which the patients were occupied in coil-stripping. Eight observations (lasting one quarter of an hour) were made during each fortnightly period and the total scores for each group are shown in Table 3.

The decrease in "immobility" score, when active conditions of supervision were introduced, and the subsequent increase when passive conditions were resumed, is obvious. The decrease in total score from period 3 to period 4 is significant ($t=4.95$, $p<=.001$). The subsequent increase in period 5 is also significant ($t=3.87$, $p<.001$). There is no significant change in the behaviour scores on the other 3 scales, but there is a small and consistent improvement in each one during the periods of active supervision.

TABLE 3
Total Workshop Behaviour Scores, for Groups
A and B, During 5 Fortnightly Periods

PERIOD	CONDITION OF SUPERVISION	IMMOBILITY		MANNERISMS		LAUGHING AND TALKING TO SELF		RESTLESSNESS

	Active conditions	88	75	16	3	62	43	40	53

3. *Ward behaviour scores* : The mean behaviour scores for Groups A and B during the 14 weeks in the workshop, are shown in Table 4. The scores representing Socially Embarrassing Behaviour show little change throughout this period and there is no significant difference between the groups. So far as Social Withdrawal scores are concerned, Group B has slightly higher mean scores throughout, though the difference between groups is not significant. There is a gradual decrease in score in both groups from weeks 4 to 8, but this is clearly not related to the activity of the workshop supervisors. The factors responsible for the temporal trends which can be seen in these data are almost certainly complex. Since no other hypothesis was put forward concerning them, no further statistical analysis has been undertaken. It should be noted, however, that the improvement in ward be-

haviour took place during a period when the patients were not receiving any medication.

DISCUSSION

The statistical analysis confirms the impression given by Figure 2, that there is an immediate increase in output in 16 out of 22 severely ill long-hospitalized schizophrenic patients, in response to additional social incentives, and that this increased motivation lasts only as long as the stimulus is applied. Such an unequivocal result raises the question as to why a similar result was not found in the experiments of O'Connor, *et al.* (10) and O'Connor and Rawnsley (12). There may be two explanations. In the first place, it has been shown that there are two subgroups in the present series of patients. Half the patients accounted for over 90% of the initial output of the group, and for all the improvement due to practice, but

TABLE 4
Mean Weekly Ward Behaviour Scores for Individuals in Groups A and B

* Active conditions of supervision. Two trials in week 13 and 3 in week 14 were also conducted under active supervision.

this subgroup contributed only 40% of the increase in output in response to additional social stimulation. The remaining patients who had a very low initial output, and who showed no improvement with practice alone, accounted for 60% of the increase in output under active conditions of supervision. O'Connor's patients were probably functioning at least at the level of the former group. In the second place, the social conditions of the present series were much more rigorously controlled, and a more sustained and intensive social stimulus was applied. In O'Connor's work the stimulus was applied uniformly at specified intervals, during 20-minute trials, by experimenters with whom the patients were unfamiliar. In the present project, most stimulation was given to patients who were working least, though every patient was encouraged, and the whole group was aware of the change in routine throughout the period of active supervision. The 2 supervisors were familiar staff nurses who were with the patients all day and every day for several months.

The flat learning curve, to which O'Connor drew attention, is clearly evident in the present work. There is a very marked handicap as measured by the output on the very simple industrial work provided. The fact that, though output was increased under conditions of social stimulation, it did not remain at the higher level when the stimulation was withdrawn, differentiates these patients from the imbeciles in O'Connor's experiment(11).

The decrease in immobility concomitantly with an improvement in output during periods of active supervision is to be expected. Three of the scales which were rated according to observations made during time-sampling of the patients' behaviour, concern activities which are, in part, alternatives to working. If the patients work harder, the time spent in inactivity, mannerisms or restlessness is likely to be diminished. When these ratings are summed for trials 56-79, the resulting scores show a very high correlation with mean output over the same period ($r = -0.93$).

Ward behaviour did not show any corresponding fluctuation during periods of active, compared with periods of passive, supervision. This accords well with the ex-

periences of the other investigators to whom reference was made earlier. There is no generalisation of response from the specific situation in which extra stimulation is provided, to other social situations. The overall improvement and later fluctuation in ward behaviour may possibly be explained in terms of the type of work done—in particular the degree of interest shown by the patients in the different types of work—or it may result from a complex of factors including changes in the attitude of the rating charge nurses.

There is a significant increase in the output of relatively complex work (box nesting) as well as in performance on sleeve folding when active supervision is introduced. The increase is not, however, proportionately as great. The importance of the results with complex work lies in the fact that not only does output increase under active conditions of supervision but it decreases significantly when passive conditions are resumed.

The clear cut way in which these patients responded, with very little latent period, to extra social stimulation, and particularly the sharp drop in output when the stimulation was discontinued, is difficult to explain in terms of learning theory. A physiological process is suggested. Cozin, *et al.*(3) have described something similar in senile patients. Tizard and Venables(15) and Venables(16) have described the improved efficiency of performance of withdrawn chronic schizophrenic patients under conditions of increased background stimulation, and Venables(16) has since postulated a change in level of reticular activity to account for this. However, it is premature to speculate further along these lines in accounting for the present findings.

The way in which other changes in the social environment immediately affect performance is demonstrated by the increase and subsequent decline in output in Group A, while B was being selectively encouraged, and also by the decline in output in Group B when substitute supervisors had to be introduced for 3 trials. There is little doubt that many such "random" influences are occurring all the time in a hospital ward, and the high reactivity which many patients in this series show, may account for the fact

that the performance of schizophrenics is always found to be extremely variable.

The clinical value of active, as compared with passive, supervision for these patients in an occupational therapy department or sheltered workshop is difficult to assess. It is a sound principle of rehabilitation to give exercise to functions which have become disused following illness or injury, in the hope that partial or complete recovery may eventually occur. "Institutionalism," in chronic schizophrenics, may be largely due to the fact that apathetic patients do not actively use their faculties and, in a crowded and understaffed ward, it is difficult to give the proper medical and nursing attention which would keep residual mental and physical functions at the optimum level.

Whether such active remedial care is, in itself, therapeutic, cannot be decided from such a short experiment as this one. There is no evidence, over 16 weeks, that the patients are much different in mental state or behaviour from when they started, though the measures used are admittedly extremely crude. On the other hand, improvement in output was still taking place in certain patients after 200 hours of practice, and it is unlikely that these experimental conditions provided the optimum environment for improvement to occur. Further experimentation is needed in order to discover whether chronic schizophrenic patients may reveal unexpected residual assets under conditions of prolonged and intensive re-education of specific faculties.

SUMMARY

: Twenty-two long-stay severely ill male schizophrenic patients were employed in a hospital workshop for 16 weeks. They all lived in one villa where the standard of social treatment was high. The two workshop supervisors were a male and a female staff nurse. The sex of the supervisor did not influence the results. The conditions of supervision were varied experimentally. There was a sharp increase in output (on a simple sleeve folding task) whenever social incentives were introduced, and a sharp fall whenever passive conditions of supervision were resumed. The 10 patients with the highest initial output, together with 1 other (ranked 13 on initial output), accounted for

over 90% of the output under passive conditions, and for all the improvement due to practice. However, they contributed only 40% of the improvement due to additional social incentives. The remaining patients, therefore, functioned at a very low level relative to the initially high scorers and showed no practice effect, but 7 of them responded very markedly to encouragement. Time-sampling of workshop behaviour showed that the increase in working activity, under active conditions of supervision, was accompanied by a significant decrease in various abnormalities of behaviour (immobility, mannerisms and restlessness). Ward behaviour was unaffected.

APPENDIX A

IMMOBILITY

3. Sitting or standing with minimal movement, *e.g.*, head sunk on chest, eyes closed or half-closed, only very occasional movements such as lifting head or shifting position.

2. Some movement, *e.g.*, staring round workshop, a little work, some fiddling with scraps, rubbing face or yawning, or rare mannerisms. Mainly just sitting.

1. Moving most of the time, *e.g.*, working, fiddling, shifting position, but occasionally remains in one posture without movement.

0. Constantly moving—either working or restless movements.

MANNERISMS (stylised movements which are clearly not random as in fiddling with a scrap of paper, but meaningful to the individual)

3. Practically continuous during observation period.

2. Frequent mannerisms, or for more than half the observation period.

1. Occasional manneristic movements.

0. No mannerisms seen.

MOUTH AND LIP MOVEMENTS, TALKING AND LAUGHING TO SELF

3. Frequently talks or laughs out loud throughout observation period.

2. Occasionally laughs or talks out loud. And/or: overt continuous obvious lip movements, but soundless.

1. Occasional obvious muttering, or continuous chewing, teeth clenching or covert lip movements.

0. No mouth or lip movements.

RESTLESSNESS (include all movements not connected with efficient work but excluding mannerisms).

3. Wandering around workshop throughout observation period.

2. Some wandering around, or constant fiddling (*e.g.*, playing with elastic band or scraps of paper, rubbing face and hands, *etc.*).

1. Some fiddling or staring around.

0. No restless movements.

APPENDIX B

OUTPUT ON AN INDUSTRIAL TASK AS AN OBJECTIVE MEASURE OF IMPROVEMENT IN CHRONIC SCHIZOPHRENIC PATIENTS

In the preceding paper an experiment was described in which 22 severely ill chronic schizophrenic patients were occupied on industrial tasks under varying conditions of supervision. All drugs were removed 2 weeks before the patients entered the workshops. The output the patients achieved throughout the experiment was very low, but it was clearly demonstrated that 11 of them improved with practice, and that 16 out of 22 improved further when extra social incentives were introduced. It was intended to combine this exercise with a drug-trial, but the supply of work ran out after the patients had been receiving trifluoperazine or placebo for only 3 weeks, and an adequate trial was not therefore possible. The method used, however, is thought to be of sufficient interest to justify a technical note on procedure.

Two groups of patients were matched on their industrial output during 18 2-hour trials (33-50). These groups were not significantly dissimilar in respect of age, length of stay in hospital, ward or workshop behaviour scores. One group (6 Group A and 5 Group B) received trifluoperazine 10 mg. b.i.d. The other group received similar inert tablets. Only the clinician (R.K.F.) was aware of the identity of the experimental

and control group patients. Tablets were introduced on the evening before trial 56. Trials 56-69 were conducted under passive conditions of supervision, and trials 70-79 under active conditions. After the patients had been receiving tablets for 6 weeks, more complicated work was introduced (trials 83-94).

The output of the two groups in respect of simple sleeve folding (trials 33-79) and box nesting (trials 83-94) is shown in Table 1. Although the groups are closely matched during trials 33-50, they diverge somewhat so that the placebo group is superior, during trials 51-55 (before tablets were started)—the difference is not, however, significant ($t=0.89$). During trials 56-69 (passive conditions of supervision) there is no change in the relative outputs of the experimental and control groups. When active supervision is introduced (trials 70-79), the 2 groups again become equivalent in output. There is no hint of a drug effect in these figures.

When the more complicated work is introduced, the group of patients receiving trifluoperazine achieves a higher output than the placebo group, under both active and passive conditions of supervision. The difference is not, however, statistically significant (under passive conditions, $t=0.82$).

Clearly the conditions of the experiment do not allow for a conclusion as to whether there is an improvement due to trifluoperazine after 6 weeks on the drug, since output on the two kinds of work is not comparable. However, the reversal of the relative levels of output in the 2 groups does suggest a drug effect.

This method is potentially valuable for testing the efficacy of new drugs in this type of patient, where the handicap is so severe

TABLE 1
Group Output per Trial, During 9 Blocks of Trials in a Group of Patients Receiving Trifluoperazine and a Group Receiving Placebo

	BLOCK	TRIALS	TRIFLUOPERAZINE	PLACEBO
Sleeve folding	3	33-50	3954	4079
	4	51-55	2880	4630
	5	56-69	3278	4886
	6	70-79	6910*	7390*

* Active conditions of supervision. (Drug or placebo treatment commenced with trial 56.)

that even small degrees of improvement should be noticeable. It should also be possible to discover whether there is any interactive effect between drug and social treatment.

Future trials should only be undertaken when a long run of work is available. Plenty of time is needed for preliminary matching before drugs are introduced, and at least 8 weeks trial on the drug should be allowed for. Matching should take account, not only of initial level of output, but also of practice effects and the effect of social stimulation (unless this is rigorously controlled). Practice effects are difficult to avoid by waiting until all patients have reached a plateau. In this experiment, several patients were still improving after 200 hours of practice.

A COMPARISON OF PROMAZINE AND PARALDEHYDE IN 175 CASES OF ALCOHOL WITHDRAWAL¹

WILLIAM T. HART, M.D.²

The purpose of this study is to compare the use of paraldehyde alone, promazine (Sparine) alone, and a combination of paraldehyde and promazine in the treatment of the alcohol withdrawal syndrome.

This syndrome follows prolonged use of alcohol and includes anxiety, agitation, tremor, loss of appetite, and insomnia. Other more severe symptoms that may be present are nausea and vomiting, convulsions, and delirium tremens. Experimental work confirming this view of the alcohol withdrawal syndrome is presented by Fraser(1) and Wikler(2).

Delirium tremens was diagnosed in this study when the patient manifested simultaneously, while he was in the hospital: 1. Hallucinations and/or delusions; 2. A sensorial deficit. Alcoholic hallucinosis, which differs from delirium tremens by the absence of the sensorial deficit, was excluded from this study. I feel, as do many others, that alcoholic hallucinosis is a release of an underlying psychoses rather than a symptom of alcohol withdrawal. Bleuler(3) gives a description of the peculiar nature of the hallucinations of the patient with delirium tremens and indicates how they differ from those of alcoholic hallucinosis. He points out that the combination of anxiety with euphoric humor (grim humor) is a pathognomonic sign of delirium tremens. He states that when auditory hallucinations are present the diagnosis of schizophrenia must always be considered. Finally he finds in patients with alcoholic hallucinosis that a long-standing schizophrenia is invariably present.

Convulsions during the period of withdrawal were of particular interest because,

although not a frequent complication, they are a serious complication. Also, there have been indications in studies by Szatmari, Barsa, Reinert and Fazekas, that the use of phenothiazine derivatives increases the possibility of convulsions(4-7).

There have been many treatments of the alcohol withdrawal syndrome. Romano(8) reviews the early studies on delirium tremens and the concepts of its etiology and therapy. Block(9) reviews current therapies of the alcohol withdrawal syndrome and emphasizes the value of the phenothiazine derivatives. The more recent literature describes the use of both the phenothiazine derivatives and other agents(10-17). Friedhoff and Zitrin(13) indicate that treatment with the phenothiazine derivatives or with paraldehyde is equally effective. Also, in view of some clinical impressions that I had regarding seizures as a complication of phenothiazine therapy, I wished to evaluate this problem in the treatment of the alcohol withdrawal syndrome with the various drug therapies used in our study.

MATERIALS AND METHODS

The Monroe County Psychiatric Hospital Unit is a diagnostic unit where patients are admitted for short-term screening and diagnosis of psychiatric illnesses. The Unit also admits alcoholics on a voluntary basis from the community and under commitment from the courts and jails. Alcoholics constitute about 450 admissions per year or approximately one-third of our total admissions. Men comprise most of these alcoholics and our study was limited to men only. The bulk of the alcoholics from the community seek admission to terminate their alcoholic episodes, usually because they are in physical distress. The courts and jails send alcoholics that are too sick medically or psychiatrically for their facilities. The function of the Unit with respect to the alcoholic is to terminate the withdrawal syndrome, and then the patient is referred to his private physician, the alcoholism clinic, alcoholics anonymous, or returned to the court or jail. There is no

¹ Drs. Orris Clinger, Elmer Gardner, Gerald Claser, Harold Miles, and Holland Taylor assisted in the collection of data from patients and made many helpful suggestions. Drs. Elmer Gardner and Howard Iker helped with the statistical analyses.

² Monroe County Psychiatric Hospital Unit and the Dept. of Psychiatry of the University of Rochester School of Medicine and Dentistry, Rochester, N. Y.

systematic psychotherapy in the hospital although an attempt is made to maintain a psychotherapeutic attitude among personnel.

On admission, each patient had a physical examination and routine laboratory work, and during his hospital stay was seen repetitively by both internists and psychiatrists.

Patients were excluded from the study for the following reasons: 1. If they had a severe physical or psychiatric illness other than that due to the alcohol withdrawal; 2. If they were taking large amounts of other drugs; 3. If they were drinking less than 5 days out of the previous 10 days before admission.

All the patients admitted during the first 4-week period of the study were treated with promazine and paraldehyde. During the second 4-week period all were treated with promazine alone, and during the third 4-week period with paraldehyde alone. This rotation of treatment was then repeated, the study lasting a total of 24 weeks.

All the patients in all groups were given vitamin B complex intramuscularly for 3 days and multivitamins orally, daily while in the hospital. The basic orders, which could be varied to fit the patient's needs, were as follows for the different groups: 1. The promazine-paraldehyde group had an initial intramuscular injection of 100 mg. of promazine, followed by 100 mg. by mouth q.i.d. They also received 6 cc. of paraldehyde every 4 hours by mouth, as needed. 2. The promazine group had an initial injection of 100 mg. of promazine intramuscularly and then had 100 mg. of promazine every 3 hours by mouth, as needed. 3. The paraldehyde group had 6 cc. of paraldehyde by mouth every 3 hours, as needed.

A form was used for recording results, entering "yes" or "no" for the following categories: 1. Slept well; 2. Ate well; 3. Agitated and anxious; 4. Vomited; 5. Convulsed; 6. Confused; 7. Delusions and/or hallucinations.

Each shift of nurses recorded their observations on the form at the end of their shift. Thus in the course of the day the patients were observed by three different shifts of nurses. Six days a week the patients were seen by one of our two internists and their observations recorded. The internist saw all

patients on the days he made rounds and each internist made rounds 3 days per week. Each patient was also followed by one psychiatrist who saw his patients about 3 times per week and recorded his observations.

The study grew out of an interest of both psychiatrists and internists involved in the study, as to the relative effectiveness of paraldehyde and promazine in the treatment of alcohol withdrawal. The nursing staff were told of the study and its purposes and the recording of information was an extension of their nursing notes.

The measurement of the various categories was gross; if the patient slept continuously between midnight and 7 a.m. he slept well; if he cleared his tray, he ate well. Agitation and anxiety were recorded as positive if there were any indications of either on gross inspection. Confusion was positive if the patient was disoriented for time and/or place. Delusions and hallucinations were positive when observed in the patient while he was in the hospital. The day of discharge was determined by the psychiatrist and was primarily a reflection of the categories of sleeping, eating and anxiety, and agitation returning to normal. Also involved was the clinical judgement that the alcoholic had temporary control of his drinking.

RESULTS

During the 24-week period of the study, 222 patients with alcohol withdrawal were admitted to our Unit. Of these, 47 patients were excluded from the study (see Table 1). This group was 21% of the total (in-

cluded was one patient from the promazine group who had had several seizures before admission. After admission he had several

more seizures with temporary respiratory arrest. Because of the severity of his illness, he was transferred to another hospital for acute care. Another patient included in this group had a seizure before medication and sustained a basilar fracture of the skull with subarachnoid hemorrhage. He was treated with paraldehyde and also was transferred to another hospital. Both patients survived but were not followed in our Unit and so were excluded from the study). Table 2

Total Number of Patients in Treatment Groups and Numbers with and without Delirium Tremens *

	Promazine	Paraldehyde	Promazine-Paraldehyde	Total
Total patients withdrawal syndrome	57	56	62	175
Withdrawal syndrome without delirium tremens	44	47	45	136
Withdrawal syndrome with delirium tremens	13	9	17	39

* The total number of patients (175) represents 157 individuals of whom 12 had two admissions, and 3 had 3 admissions.

shows the total number of patients studied in the various treatment categories. This is

FIGURE 1
Percent of patients in the hospital on each hospital day with different therapies *

* The hospital day number indicates the end of that day. The first day was of varying length, depending on the hour of admission. For purposes of compilation the day of admission was counted and the day of discharge was not counted.

broken down into sub-groups of alcohol withdrawal, with and without delirium tremens.

Figure 1 plots the per cent of patients remaining in the hospital at the end of each hospital day for the different therapies. It can be seen that the promazine group left the hospital earliest and that the paraldehyde and promazine-paraldehyde group follow approximately the same curve. At the end of the fourth day, for example, 28% of the promazine group, 66% of the paraldehyde group and 61% of the promazine-paraldehyde group were in the hospital. The average stay of the promazine group was 4.09 days and that of the paraldehyde group 5.18 days. When analyzed statistically there is a significant difference between the promazine and paraldehyde groups.³

Graphs with similar curves were obtained when the following categories were plotted: 1. Per cent of patients agitated and anxious on each hospital day with different therapies. 2. Per cent of patients sleeping poorly on each hospital day with different therapies. 3. Per cent of patients eating poorly on each hospital day with different therapies.

At the end of the fourth day, 12% of the promazine patients and 55% of the paraldehyde patients were anxious and agitated. When the paraldehyde and promazine groups were compared as to duration of anxiety and agitation, the promazine group showed statistically significantly shorter duration.⁴

Promazine was also found to be significantly more effective in controlling sleeplessness than paraldehyde.⁵ A similar difference was found in patients returning to normal eating patterns, with promazine being more effective than paraldehyde but not as effective as in the other categories.⁶

The groups of patients with delirium tremens treated with different therapies were graphed for days in the hospital and for duration of anxiety and agitation. These graphs were similar to those of the total groups. Under promazine therapy, there

³ $T = 4.30$ with 111 df. P is less than .01.

⁴ $T = 5.02$ with 111 df. P is less than .01.

⁵ $T = 3.15$ with 111 df. P is less than .01.

⁶ $T = 2.50$ with 111 df. P is less than .05 and greater than .01.

was earlier discharge from the hospital and earlier disappearance of agitation and anxiety but the difference was not statistically significant. In these cases again the statistical comparison was between the promazine and the paraldehyde groups.

Convulsions and Vomiting: In the combined groups, a total of 14 patients had seizures of the grand mal type. However, 2 patients had seizures in the hospital before any medication had been given and are not included in our figures. Table 3 shows

TABLE 3
Number of Patients with Grand Mal Seizures in
Various Treatment Groups

	Promazine	Paraldehyde	Promazine- Paraldehyde
Withdrawal syndrome without delirium tremens	2	2	0
Withdrawal syndrome with delirium tremens	3	0	5
Total number of seizures	5	2	5

the distribution of the seizures in the various groups. There is not a statistically significant difference between the various treatment groups.⁷

One of the promazine group had convulsions before admission and 2 convulsed a few minutes after receiving the initial injection of promazine. Most of the promazine seizure group were treated with barbiturates after they convulsed, but 2 were continued on promazine alone without further seizures. The paraldehyde and promazine-paraldehyde groups were treated only by increasing the paraldehyde, after seizures occurred.

Vomiting was approximately the same for all groups. There were 6 patients in the promazine group who vomited at some time during their hospital stay, 7 in the paraldehyde, and 7 in the promazine-paraldehyde group.

Clinical Impressions: A complication of promazine therapy that offered difficulty

was postural hypotension. This was very common and was manifested as "lightheadedness" and/or "dizziness," and occasionally a patient would fall to the floor. Blood pressures were not taken routinely as part of the study. However, when blood pressures were taken on patients with the above symptoms, the readings were found to drop markedly when the patient went from the lying to standing position. This was most prominent the first day or two of promazine therapy and would disappear at times without changing dosage or with lowering the dosage. We did not have to discontinue treatment on any patient because of hypotension.

All personnel involved with the patients found them much more manageable and cooperative without paraldehyde, whether it was given with or without promazine. With paraldehyde, patients were constantly asking for more and upsetting ward routine. Also, they were more agitated, wandered about more, and disturbed other patients. Overall, the ward was more disturbed and tense. Of the patients who had experience both with paraldehyde and with promazine alone, comments varied. Some patients preferred the treatment with promazine while others preferred treatment with paraldehyde.

COMMENTS

The results of the study indicate that promazine is preferable to both paraldehyde and promazine-paraldehyde therapy in the treatment of alcohol withdrawal. It should be noted that in the treatment of delirium tremens, there was not a significant difference between promazine and paraldehyde therapy, though there was a trend favoring promazine therapy. In the categories of early discharge, duration of anxiety and agitation, and time required to be eating and sleeping well, promazine by itself showed the greatest efficacy. In terms of ward management, all personnel agreed that problems were decreased with the use of promazine alone. With the use of promazine therapy, it seems to me that the majority of our patients could have been managed in a general hospital.

Convulsions were more frequent in both treatment groups in which promazine was

⁷ Comparing all three groups: $\chi^2=1.318$. P is greater than .5 and less than .7 with 2 df. Comparing the promazine and paraldehyde groups: $\chi^2=1.287$. P is greater than .2 and less than .3 with 1 df.

used, although not significantly so. This was a surprise for two reasons : 1. That convulsions are a symptom of alcohol withdrawal and accordingly, alcohol or a similar drug would seem the treatment of choice ; 2. That the tranquilizers, as indicated previously, seem to increase the likelihood of seizures.

Postural hypotension was a common problem with promazine with the main apparent danger being that of a hypotensive episode associated with a fall. In this study group, however, there were no known serious complications of hypotension. It should be noted that no routine measurements of blood pressures were made.

SUMMARY

A comparison was made of the treatment of the alcohol withdrawal syndrome with either promazine, paraldehyde or promazine-paraldehyde combined. 175 patients, 136 without delirium tremens and 39 with delirium tremens, were studied.

Promazine was found to be better than either paraldehyde or promazine-paraldehyde combined, in the categories of early discharge from the hospital, decreased agitation and anxiety, and return to normal eating and sleeping patterns.

When the delirium tremens group treated with promazine was compared with the group treated with paraldehyde, there was not a significant difference.

Vomiting was approximately the same in all groups. Convulsions were more frequent in the groups treated with promazine, but not significantly so. Postural hypotension was a frequent complication of promazine therapy.

Ward management of the patients who did not receive paraldehyde was easier than

of those who did receive it. It appeared that with the use of promazine many of the patients could have been managed in a general hospital.

THE PUERTO RICAN SYNDROME

CAPTAIN ROBERT D. MEHLMAN, M.D.¹

In very recent years it has become a rather common practice both on the Island of Puerto Rico, in areas of the Continental United States such as New York City where there are large concentrations of Puerto Rican patients, and in the Armed Services where Puerto Rican troops are frequently seen medically, for physicians to make a diagnosis of Puerto Rican syndrome or "ataque." Indeed, although few articles have been written describing these syndromes in detail, most of these articles and the consensus amongst those who make the diagnosis regularly is that the syndrome is a cultural phenomenon which is especially prevalent in this particular group of people(1, 2, 3). It has also become a take-off point for at least one treatise upon the subject of social psychiatry or cultural psychiatry and has been linked with pleas for further understanding and investigation of cultural phenomena and their impact upon psychiatric disease(1).

The syndrome has been variously described but in general there are several criteria which are characteristic. Certainly the most prominent is the bizarreness combined with extreme fright, agitation and personal violence. The descriptions include syndromes mutism, pseudoepilepsy, violent movement, bizarre detached uncommunicative violent attitudes, self-mutilation, and the full range of psychotic behavior from posturing of a catatonic sort to coprophagia (2, 3). This is the most spectacular aspect of this syndrome and in this lies the key to understanding the confusion that has arisen with the evolution of this new term.

The following are sample case histories written from Rodriguez U. S. Army Hospital files. All of them were referred to the hospital with the diagnosis of "Puerto Rican syndrome."

Case 1.—The patient was a 23-year-old Army private who became acutely disturbed suddenly one day while sitting in his barracks. He got

up, ran around the room, jumped on everybody's bed, screamed and yelled and had to be restrained. In the process of being subdued, the patient became almost rigid, was breathing very heavily, rolled his eyes up so that only the whites were visible, foamed at the mouth and trembled all over. He was admitted to an Army hospital in the Continental United States where he remained for several weeks. During his hospitalization, there were several similar episodes somewhat milder but always marked by subsequent amnesia and mild confusion. From each of these episodes he experienced a complete and spontaneous recovery. During subsequent examinations, the patient reported that he had intermittent headaches and giddiness for approximately 4 years always in relationship to his feelings of anger. He stated that every time he seemed angry at somebody, the feelings would come over him. During subsequent examinations, the patient began to recollect that during the course of his training at his last station, prior to his hospitalization, he had become terribly angry at his sergeant who, he said, was unfair but towards whom he was not particularly paranoid. He detailed many complaints about the sergeant and with a great deal of anger. During the examinations, the patient again began to experience giddiness, headache, and had trouble finding words. When the subject was dropped and he was allowed to go back to the ward, he experienced a complete remission of his symptoms.

Shortly after being transferred to this hospital, the patient was discharged back to a trial of duty and very soon thereafter experienced an episode similar to the ones described above making it clear that he could not function on duty under ordinary conditions.

Subsequent information elicited from prolonged diagnostic interviews with this patient revealed that his symptom formation, prior to his entry into the service, was almost always exclusively centered around his anger towards his father and he described many relevant incidents. Indeed, during his trial of duty, described above, the patient had gone home on leave and experienced again angry feelings in relation to his father which he was able to describe in considerable detail before again experiencing his symptom in the interview.

This patient was evidently suffering from an acute dissociative reaction of an hysterical sort

¹ Chief, Psychiatric Section, Rodriguez U. S. Army Hospital, Fort Brooke, Puerto Rico.

from which he recovered rather rapidly with proper treatment.

Case 2.—The patient was a 20-year-old Puerto Rican recruit who had gone AWOL for several days. He was brought to an Air Force base hospital on another part of the Island because he was running down the street with no clothes on and experiencing a great deal of anxiety, bizarre behavior and was screaming incoherently.

During hospitalization he settled down rather quickly and several attempts to send him home on convalescent leave were made. During each of these there was an exacerbation of the acute syndrome. At one time, while driving along the street in a public taxicab he tried to get out of the car at high speed because, he stated, he had a tremendous fear of staying in the car. He stated it was not the speed but that he just felt the need to get out and go home. During each of these acute exacerbations there was a great deal of violence and bizarre behavior, as noted above, associated with hyperventilation, anxiety, and confusion.

In later prolonged diagnostic interviews, it became clear that the patient was actively hallucinating almost continuously and that whenever he was away from home, he heard voices which told him terrible things were happening at home. Specifically, the voices were those of his mother who said that the furniture was being moved out of his house. As the patient was able to verbalize further, it became clear that his acute panic had been precipitated by concern over his wife's impending delivery of her first child and that many of the fantasies and delusions the patient talked about were related to this. He had fantasies of his wife running around with other men and was tentatively paranoid about everybody who had anything to do with her. He was particularly concerned with his relationship with his father from whom he was inadequately seeking financial help in order to finance the setting up of an adequate household. During the period of his acute upset, the patient was unable to verbalize coherently, had a flight of ideas and was grossly tremulous and obviously very much frightened. At times on the ward, he smeared feces all over himself and appeared almost catatonic. He was able to return home after several weeks hospitalization.

Here it is equally clear that the patient was suffering from an acute dissociative response which was part of an acute homosexual panic or an acute schizophrenic turmoil from which he again recovered in the course of time to his

premorbid state where psychosis was not grossly evident.

Case 3.—This patient had been AWOL from his unit for several days. Shortly after being apprehended by the military police, he was brought to this hospital, mute, uncooperative, violently twirling his arms around and hyperventilating. He refused to cooperate in examination procedures and intermittently cried profusely. He stated, in between periods of mutism, that he did not know who he was. He would pull his testicles and stated that he did this in order to see blood because he liked to see blood. He would occasionally hold his head as if he had a headache but there was no explanation of this forthcoming from the patient.

During the course of hospitalization, it was clear that he was not eating and another patient was asked to encourage him to eat. The patient gradually began to eat more although he only very slowly gave up his symptoms. His entire symptom pattern returned each time he was approached by a new interviewer and indeed when the question of his going back to duty was raised, he stated that he would burn all his clothing and made numerous threats about what he would do if this course of action was taken. At this point it became evident that the patient was malingering. When confronted with this, he became very angry, turned around to the patient who had been feeding him and said, "See, if you hadn't been so insistent I would have gotten away with it."

Here again the patient manifested much the same symptoms but was not suffering from a psychiatric disease as we know it but was feigning the so-called "ataque" for secondary gain.

Case 4.—The patient, a 19-year-old recruit, was admitted to the hospital confused, disoriented, moving his head back and forth, and hyperventilating. This episode subsided during the admission procedure, and when he was examined the patient stated that during his entire stay in the Army, he has been in continual trouble particularly for not carrying out orders. He stated that he had so many thoughts in his mind that, at times, he could not hear other people and was not aware that they were around. He stated that he hears people's voices but he is not sure what he hears. He later stated that for many years he had the feelings that there were people talking with him and they lived in his left ear.

Each morning, on awakening, he would go around the ward making bizarre gestures with both hands as if he were placing something from one position to another. As he became

more comfortable talking about this, he stated that the people in his left ear turned the world around each morning in order that he would not see them and that he was turning it back. He said that they have been doing this to him for many years. During his hospital stay, there were intermittent periods of inappropriate laughter and the patient indulged in various gestures that were incomprehensible to the ward personnel. He would respond to his hallucinations actively.

On questioning the patient's parents, it was clear that he had been withdrawn, isolated and had made some reference to the voices and the world being turned around many times, and that although symptoms had been present since he was about 13 or 14 years old he had never been so acutely upset as at the time of his admission.

This patient is a chronic schizophrenic, who was diagnosed as suffering from an "ataque" since he manifested almost the same symptoms as all the others so diagnosed, but who was found to be suffering an acute upset in his chronic schizophrenic illness.

Case 5.—The last patient was an 18-year-old recruit who was found wandering around the post on the night of his admission to the hospital. When an effort was made to talk with him, he began to fight and struggle hitting out at the persons who attempted to talk with him and struggling violently. He bit, kicked, and yelled and when finally apprehended became grossly tremulous, hyperventilated, foamed at the mouth and became mute. Following this, he appeared to make futile efforts to speak and would write incomprehensible symbols when offered a pencil and paper. The patient had recovered substantially by the next day and when questioned closely about what had been going on in the last several days, he stated that just prior to the period of his acute upset for which he had complete amnesia, he had failed his English language test after not trying very hard, primarily because he wanted to get out of the service and return to his father's farm where he was needed to work.

Subsequent interviews indicated a great deal of ambivalence about his return to work and it became clear that the conflict involved lay between returning to the protective but subservient position of working for his father and the independence of being in the service which he wanted a great deal.

This fifth example is very similar to the first in that the patient was neurotic but instead this time represents an acute conversion symptom.

All these cases were seen by several physicians as outpatients as well as inpatients before being referred to Rodriguez U. S. Army Hospital, psychiatric service. They were taken from a series of 400 patients seen during the course of a two-year period at this hospital. During this entire time, no patient was seen whose case was not readily diagnosable in terms other than Puerto Rican syndrome and no need was felt to use this term. Moreover, when these patients are considered in the situations under which they were referred to the hospital, it becomes evident why the tendency to invent a new name for a psychiatric syndrome based upon cultural phenomena is disturbing to the clinical psychiatrist.

These patients diagnosed as Puerto Rican syndrome represent the most diverse forms of psychiatric disease. Perhaps the major quality they do have in common is the fright they elicit amongst those who are unaccustomed to such phenomena in patients which usually stems from violence, the severe dissociation and the extreme momentary isolation of the patient involved in an acute psychotic process. Beyond this point, however, there are a very few similarities. To invent or use a term which tends to class all these individuals in one category poses the ever present danger, first of failing to be aware of what the real disease process is; secondly, the failure to understand the difference amongst these various syndromes makes it impossible to apply the appropriate means of treatment.

Certainly, efforts to help the patient in the past on the basis of the superficial diagnosis of Puerto Rican syndrome can have been successful only by accident and by reason of the relatively self-limited nature of the acute upset and not through calculated and effective maneuvers on the part of the physician. For instance, the man suffering from the acute dissociative reaction on a neurotic basis, who indeed is only momentarily psychotic, must be confronted with his disease very quickly and helped to accept responsibility for that which he is capable of accepting responsibility for. In Puerto Rican patients very often the issue in this situation involves the overwhelming awareness of the patient's own anger which, as in our patient above, lit up earlier unresolved

feelings with respect to anger and feelings towards his parents. He had never worked out his feelings with respect to his father and his anger towards his sargeant was quite clearly a displacement of these unresolved feelings. Every time the patient came close to awareness of his wish to kill his father, he had an acute "ataque" or dissociative reaction. Any effort to help this man must take cognizance of the fact that this is an acute effort to avoid responsibility for certain feelings, and help the patient acknowledge, accept, and bear responsibility for them in order that he might then go on to effective integration of the feelings as part of his total personality.

The second patient, who was suffering from an acute schizophrenic turmoil state or an acute homosexual panic, was clearly frightened in a way that only a person in an acute panic state can be frightened. He had clearly felt that he had died at the point of his acute upset. Any effort to treat this as a mature, genital situation and failure to see the oral dependent aspects, in relationship to the acute illness, would be a failure to basically understand what was happening to this man. Certainly if he were treated in the same way as a person suffering from the acute dissociative reaction or the acute conversion reaction, one could only make him sicker in that he was unquestionably a person with an overwhelmed ego attempting to deal with issues of a very primitive and primary nature. The approach to this man had to involve the combination of limit-setting and attempting to form a relationship over a reasonably long period of time before he could give up his psychotic process. In contrast, the neurotic suffering from the acute dissociative reaction who could re-constitute as soon as the demand that he accept responsibility for that aspect of his feelings he was clearly capable of bearing was made effectively enough through clarification, was a far different person and this attitude could only be taken to the patient suffering from the acute turmoil state.

With the third patient who was unquestionably malingering, the only appropriate move was the one which was made, namely that the matter was immediately clarified with the patient and he was discharged from

the hospital with the complete resolution of his symptoms.

The fourth patient, the chronic schizophrenic, who, in having an acute episode, was not becoming sicker but, if anything, making an effort towards dealing more effectively with people, had to be handled according to his special needs. If he were discharged from the hospital, as was the psychopath, or matters clarified with him as extensively as is necessary with the neurotic, and his symptom formation ignored as it had to be with the neurotic, he would unquestionably have withdrawn once again to his hebephrenic state and given up his awkward, abortive move in the direction of help. He also had to be separated clinically from the acute schizophrenic who was suffering from a turmoil state in that although many of the symptoms were bound to be quite similar, the chronic underlying disease must be recognized as the premorbid state and the efforts to reach out to people must be dealt with most specifically. The sick, awkward efforts in this case are not regressive phenomena but efforts to reach out, and must be treated as such along with the necessary efforts to limit-set and help the patient be less frightened.

Attempts to formulate the treatment and the theory behind the treatment of these various kinds of diseases above can only be partial here and involve many potential areas of disagreement. However, regardless of the school of psychiatry or the manner of approach to this problem, these are separate disease entities just as the patients are separate and the issues involved are unique to the patient even amongst the disease categories.

The danger here is over-generalization, over-simplification, over-modernization that takes us away from the patient. This is indeed a danger of social psychology or social psychiatry as a science⁽⁴⁾ in clinical practice in that as soon as one steps away from the individual patient in psychiatry, the individual is lost and the perceptions become inaccurate. This does not mean that generalizations or theoretical considerations should not be made but it does mean that they can only be used with the greatest care to maintain respect for the individual patient and his own dynamic disease process.

When cultures are considered and certainly the Puerto Rican culture may be considered along the lines that have been attempted with respect to the Puerto Rican syndrome, it becomes very clear that certain special aspects of the culture do have their effect upon the psychiatric health of many of the individuals concerned. However, in considering the individual patient, one discovers, for example, not that special disease entities are present but that the configuration of the phenomena which have been so universally observed in all peoples becomes somewhat colored by the culture. For example, one becomes aware, working with Puerto Rican psychiatric patients, that much of what is presented in the clinic or appears in the office in so many diseases centers around various aspects of anger as noted above. This is not unique but it is unquestionably a phenomenon that involved in so many of the acute, dissociative and conversion responses in the neurotic population of Puerto Rico the hostility towards an immediate object as a displacement, very much as in our first patient. In understanding these patients further, the connection with the underlying family structure is quite easily elicitable although the patients are, as might be expected, quite reluctant to delve into such matters without further conversion or dissociative phenomenon. In addition, in the other syndromes, particularly in schizophrenia, one sees an extraordinary number of people whose acute schizophrenic process was precipitated again by the inability to manage anger. This time, however, the anger lights up a much more prim-

itive process and even in those cases where the major issue was separation which is so often true with schizophrenic patients, one sees the medium of anger through which so much of this has become activated.

In summary then, it is felt that the Puerto Rican syndrome is a misnomer and that it is not a disease entity in itself but is rather distortion of certain useful perceptions in the area of social psychiatry. It would appear, from the experience at Rodriguez U. S. Army Hospital, that what has been called the "Puerto Rican Syndrome" in the past, is really a collection of various disease processes that tend to be superficially deceptively similar in a particular culture. The tendency to coin a phrase to fit a disease entity such as this in clinical psychiatry appears to be a confusion of social and clinical psychiatry which points away from the improvement of patient care and leads us, as physicians, further away from the facts concerning our patients.

PSYCHIATRIC SYNDROMES, ANXIETY SYMPTOMS AND RESPONSES TO STRESS IN MEDICAL STUDENTS

FERRIS N. PITTS, JR., M.D., GEORGE WINOKUR, M.D., AND
MARK A. STEWART, M.R.C.S., L.R.C.P.¹

INTRODUCTION

An unusual opportunity presents itself in medical students to study the prevalence and nature of psychiatric disease. The generally high level of intelligence and verbal facility among students tend to make their observations about their experiences more incisive. Further, because of the numerous stresses inherent in the medical students' course of study, there is ample opportunity for them to observe the effect of these stresses on their personalities. It is possible to answer the questions of whether the symptoms produced by these stresses are the same as those of psychiatric syndromes, particularly anxiety reactions, or deserve to be classified separately. Such a study affords the chance to see the individuals prior to the time they have had psychiatric care, which might conceivably influence either or both the symptoms and the clinical course. In addition it is of interest to note the psychiatric status of a typical medical school class. These factors appear to bear directly on the individual's success in medicine and might be considered in screening for a career in this field.

This paper, then, is concerned with the incidence of psychiatric illness in a medical school class, aspects of its nature, the incidence of isolated symptoms and the question of the differentiation of anxiety reaction as a psychiatric diagnosis and the response to stress.

SUBJECTS AND METHODS

Forty of 86 sophomore medical students were selected for detailed psychiatric interview after the entire class had volunteered for study without remuneration. Selection was alphabetical by surname; the terminal 50 were selected and the first 40 reached by phone for appointments were studied. Thirty-five are male; 5 are female. Age

range at interview was 21 to 26, with mean, median, and mode all 23 years.

Interviews ranged from 1-3 hours and in each instance medical, social, educational, and psychiatric data were obtained by one examiner (FNP) who inquired specifically about psychiatric symptoms and illnesses in family members.

A standard interview outline was used to insure that questions were consistently asked concerning symptoms of every psychiatric syndrome save homosexuality. Positive responses to any question led to detailed queries in that particular area. For the purposes of this study 25 specific and open-ended questions were added to assess anxiety symptoms and behavioral responses to the stress of major examinations. In the course of the interview a mental status evaluation was made and recorded.

Each record was thoroughly reviewed by the authors in group session; a unanimous vote was required for psychiatric diagnosis. Diagnoses were made according to the Standard Nomenclature of Mental Disorders of the American Psychiatric Association. Specific criteria for the diagnosis of anxiety reaction are those of Wheeler, White, Reed, and Cohen(1); for manic-depressive reaction those of Cassidy, Flanagan, Spellman, and Cohen(2); and for alcoholism those of Jellinek(3).

The category of "undiagnosed, but psychiatrically ill" was used to include subjects who had a seemingly significant number of symptoms but did not fit readily into one of the major diagnostic categories listed above.

The classification of personality disorders laid down in the APA Handbook was not used in this survey, though a considerable amount of data was obtained which related to the subjects' personality traits.

The authors rated each subject on the 16 most common anxiety symptoms of Wheeler, White, Reed and Cohen(1); a scale was devised with ranges of 0-32 and each subject was scored for anxiety, and for anxiety to the

¹From the Department of Psychiatry and Neurology, Washington University School of Medicine, St. Louis 10, Mo.

threat of upcoming examinations. Other symptoms in response to stress were noted.

The family history of psychiatric illness was carefully assessed by the authors in joint session. Each subject had been asked if any blood relatives ("and by relatives we mean siblings, parents, grandparents, aunts, uncles, cousins, and others") had ever received psychiatric in- or outpatient care, had psychiatric illnesses, had nervous breakdowns, attempted or committed suicide, been regarded as peculiar, or had any evidence of mental illness. The family histories were either positive or negative. When positive an attempt to accurately assess the nature of the relatives' illness was made by assessing attending physicians' diagnosis, age at onset, chronicity, treatment, course, degree of recovery, symptomatology, *etc.* A tentative diagnosis, admittedly second-hand, was thereby obtained for relatives. Family history played no part in the diagnosing of the subjects.

The incidence of certain symptoms commonly associated with psychiatric illness was abstracted and tabulated for this population sample.

RESULTS

1. *Psychiatric Illness*: The subjects fell into 5 clinical categories (Table I): not psychiatrically ill; anxiety reaction; manic-depressive reaction; depressive type; chronic alcoholism; and psychiatrically ill but undiagnosed.

TABLE I
Psychiatric Syndromes in 40 Medical Students

	n	%
M-D depressive reaction	3	7.5
Anxiety reaction	1	2.5
Chronic alcoholism	1	2.5
Ill but not diagnosed	1	2.5
Total ill	6	15
Not psych. ill	34	85
Total group	40	100%

Anxiety Reaction

One subject met criteria for anxiety reaction. He admitted recurrent anxiety attacks at frequent intervals for at least the preceding 12 years; these attacks were marked by palpitations, breathlessness, rapid respiration, subjective feelings of smothering, and a feeling of impending death. These attacks occurred fre-

quently seemingly without cause but also often precipitated by closed places, crowds, church, or embarrassment in front of a group. Other symptoms reported by this subject were chest pain, easy fatigability, fear of authority figures, frequent tension headaches, dizziness and giddiness, sighing, shakiness, trembling, excessive sweating, easy flushing, irritability, frequent yawning, over-concern with responsibility, fear of snakes and insects, insomnia for 3 hours twice in life, and depressive spirits for "a day or so every now and then." His rating on an anxiety scale was 22 out of possible 32; on anxiety symptoms in response to the stress of examination he scored only 10 of possible 32. He ranked in upper quarter of his class; there were no other positive responses on history or mental status. His mother had been clearly depressed for the preceding 5 years after a lifetime without prior evident psychiatric symptoms or illness.

Chronic Alcoholism

The one subject meeting the criteria for this diagnosis gave a history of drunkenness at least once weekly for approximately 10 years. He began drinking in his early teens with a group of comrades 5-10 years older than he; members of this group were involved in "a couple of robberies" and "some used drugs" but "drag races were as far as it went" with him. His parents and spouse considered him an alcoholic and had remonstrated with him many times to stop drinking. He admitted repeated blackouts, some early morning drinking, and missing both school and work because of drinking. Additionally, he admitted mild anxiety symptoms, trembling and flushing with embarrassment, a sensitivity to sulfa drugs, epigastric pain with alcoholic ingestion, some impulsiveness "but never do anything serious without thought," and 30-90 minute initial insomnia nightly. He denied DT's, hallucinations, paranoid ideas, confusion, serious suicidal thoughts or attempts. On mental status he appeared somewhat guarded and deliberately vague even while admitting excessive alcoholic intake and "nervousness" which had led him to consider psychiatric treatment. This patient's mother had gotten "depressed periodically over the drinking"; he described her having several weeks of sleep disturbance, anorexia, weight loss, crying spells, and ruminative thinking with recriminations over his drinking even after his marriage and separate residence.

Manic-Depressive Reaction—Criteria for significant depressive episodes were met by 3 subjects.

The first had had a 6-month episode of depression the preceding school year; prior to that time he maintained he'd had no psychiatric symptoms and that they were entirely gone at interview. He found he "suddenly felt different from classmates" for 3 months; was unable to concentrate or retain information even though he spent many hours attempting to study; and felt blue, hopeless, and agitated. His appetite disappeared and he lost 15 lbs.; he had great difficulty getting to sleep and "tossed and turned all night." His school work fell precipitously near failure. Somatic symptoms included dull frontal headaches, "lump in the throat," trembling, shakiness, and "tense feeling" all over body relieved only by extreme exercise. He denied suicidal thoughts, alcohol or drug ingestion, or family history of psychiatric illness.

The second student had had several episodes of depression in the preceding 7 years but had managed to avoid psychiatric care and compiled an enviable scholastic record till about 4 months prior to interview when an episode of marked depressive mood with hopelessness, suicidal thoughts, retardation, ruminative thinking, anorexia with 10 lbs. weight loss, blurred vision, anxiety attacks, crying spells, palpitation and other somatic manifestations developed. Constipation and sleep disturbance were denied; an inability to feel rested or to get up in the morning were particularly troubling. Drug and alcohol ingestion were denied. Subject felt "nothing" in response to threat of upcoming exams "except already hopeless depression." This subject's mother had had several typical depressions with complete recovery between episodes.

Four years previously the third manic-depressive subject had had a 12-month episode of severe depression in which he was "unable to concentrate or study or think straight." He "lost interest in schoolwork and everything," "had to fight and work to overcome inertia," and his grades fell from A to C average for that one year. He suffered ruminative preoccupation with an auto accident, developed marked anorexia and constipation, lost 25 lbs., had marked sleep disturbance which was characterized by 3-4 hours initial insomnia and in-

ability to arise in the morning so that he often missed class. "The future looked black" and he contemplated suicide. At the end of one year he recovered completely from this syndrome and again did well academically till interviewed. At time of interview he was overtalkative, euphoric, talked for two hours about family and personal history, and described sleeping only 2-3 hours per night for prior 6 months during which time he had been dating frequently, reading many novels in addition to schoolwork, having interpersonal difficulties at home, and lost 25 lbs. In short, he was at least hypomanic. This subject's father and paternal grandfather had experienced episodes of the depressive phase of manic-depressive reaction with recovery.

III But Not Diagnosed

One subject described episodes of euphoria "without regard to facts" lasting several days every 1-2 months; he also reported experiencing 2-3 day periods of exhaustion and depression every 1-2 months. When depressed he reported withdrawing from all social and scholastic activity: "just sick of the whole mess." He reported frequent obsessive concern with routine problems, infrequent anxiety attacks and sleep disturbance, infrequent headaches, excessive sweating, but denied all other symptoms. A maternal aunt in her early 60's developed "persistent hoarseness without cause as far as doctors could tell," became withdrawn and peculiar, and "went through two lifetime memberships with Arthur Murray." The father was described as "very gregarious, cheerful, and active" in a constant round of conservation activities in spite of a 100% government disability pension awarded because of chronic pulmonary tuberculosis. This subject was felt to be psychiatrically ill but undiagnosable at present.

2. *Family History of Psychiatric Illness:* Data for psychiatrically ill and not psychiatrically ill subjects are presented in a 2 by 2 table (Table 2). Fisher's exact probability formula for paired data gives probability of 0.0001, indicating that a positive family

10. Maternal uncle	Alcoholic

history for psychiatric illness is quite reliably associated with having a psychiatric illness in this study.

The ill relatives of ill subjects were genetically closer than those of well subjects and different diagnoses predominated as depicted in Table 3.

Anxiety ratings. The 16 most common symptoms (Table 4) of anxiety neurosis as reported by Wheeler, White, Reed and Cohen(1) were utilized to rate the entire group of subjects for anxiety; scale range was 0-32, scores ranged from 0-22 with mean of 3.9 and mode of 0. An identical scale was used to rate the subjects on these symptoms in response to pre-exam stress; here the score ranged from 0-22 with mean of 7.3 and mode of 8.

The anxiety ratings were compared with responses to stress of upcoming examinations. This was tested by a rank-order correlation for the entire group and a rho of

0.35 was obtained, indicating little relationship between these symptoms in this group before exams and at other times.

When anxiety ratings of the psychiatrically ill subjects and the responses to stress before exams were separated from those not psychiatrically ill (Table 5) interesting differences are immediately apparent.

Thus it would appear that ordinarily the psychiatrically ill subjects had many more anxiety symptoms than those not psychiatrically ill, but that no increases occur in anxiety symptoms for the psychiatrically ill prior to major examinations. Before exams, however, the well subjects developed anxiety symptoms with group incidence not very different from those found at all times in the ill subjects.

The additional symptoms of sudden appetite change, frequent small bowel movements, urinary urgency and/or frequency, nausea or "queasiness," and confusion were

Not psychiatrically ill (n=34)	2.4	7.0

responses to stress of exams reported in equal frequency by both psychiatrically ill and well subjects. On 0-10 rating mean for ill was 5.7 and not ill was 4.6.

On an anecdotal level, the one anxiety neurotic in our group reported half as many anxiety symptoms in pre-examination periods, stating that they were "not upsetting and a relief because I can work and do something about them by working."

Comparison of the incidence of symptoms characteristic of anxiety neurosis reported by our subjects with those reported by White and Cohen(1, 4) for anxiety neurotics, controls, and "scared soldiers" (Table 6) demonstrated that ordinarily our group resembled the control population. In response to stress or threat of upcoming major exams they resembled "scared soldiers" rather than anxiety neurotics.

Other Psychiatric Symptoms. The group incidence of certain other symptoms and behavior often found in psychiatric illness is tabulated in Table 7.

Many of these require clarification. The occurrence of these at any time in life was

TABLE 7
Frequency in Percent of 40 Subjects

Dream	87.5%
Nightmares	20 %
Syncope	32.5%

sions had to do with such things as excessive neatness, concern that doors locked at home and lights off; however, ruminative depressive thinking accounted for 3 of 4 instances of obsessions.

DISCUSSION

Psychiatric Illness. The 15% incidence of psychiatric illness in this group of 40 sophomore medical students is not, in itself, startling, but the distribution is not that previously reported for such samples. Heath (5) reported 75 of 100 cases in a Health Service (composed mainly of medical students and professional personnel) to be schizophrenic. In our small sample we found no schizophrenics; indeed only 2 cases of schizophrenia have been seen in Washington University Medical students in the past 16 years.

White, Cohen and associates(1, 4) suggest an overall urban incidence of approximately 5% for anxiety neurosis and have indicated that much higher incidences might be found in educational settings; certainly one anxiety neurotic out of a sample of 40 (2.5%) is not significantly different from this 5%.

The diagnosis of chronic alcoholism in a 23-year-old student implies a guarded professional and medical prognosis; at time of interview this subject was in serious academic and marital difficulties and subsequently withdrew from school. It was not until several months after the interview that his behavior brought him to the attention of the psychiatric service. Saslow(6) reported no alcoholism in 200 medical students seen by the psychiatric service of Washington University from 1944 to 1956.

The prevalence of manic-depressive disease is approximately 0.5% for the general population(7), but other writers(8, 9, 10) have suggested that only one in 3 to 5 instances of endogenous depression is accurately diagnosed. The 7.5% incidence of manic-depressive reaction in our sample is more in keeping with this latter idea; certainly 2 of our 3 subjects so ill were undiagnosed prior to interview.

As stated in the introduction our subjects should be considered reliable informants by reason of intellect and training. The differences found in positive family histories

of psychiatric illnesses between ill and well subjects is highly significant on a statistical level but the degree of closeness of relationship of these ill relatives is perhaps equally important. The ill subjects giving positive family history (5 of 6) all reported that at least one immediate relative (parent) evidenced symptoms of psychiatric illness. None of the relatives was examined so that our diagnoses are only tentative but a striking difference in their quality can be noted (Table 2). Thus, it appeared that psychiatrically ill second-degree relatives (aunts, uncles, cousins) suffered such diverse illnesses as alcoholism and schizophrenia, while manic-depressive reaction is the only likely diagnosis for relatives of these ill subjects.

Our attempt to demonstrate a relationship between anxiety symptoms in ordinary life and those in response to psychologic stress by means of a rating scale and rank-order correlation resulted in a rho of 0.35 which indicates that these "anxiety" symptoms are of quite different populations (or nature). The evidence that mean anxiety ratings for the psychiatrically ill do not change with stress but that mean ratings for the well subjects approach those of the ill with stress, after having been initially quite different, further supports this idea. This might lead some to such suggestions as "the psychiatrically ill are obviously under constant stress—hence the anxiety"; against this we cite the negative rank-order correlations and the anecdotal description of qualitative difference reported by our subject with anxiety neurosis.

The comparison of the incidence of anxiety symptoms in our group with those found by Cohen and White(1, 4) in their anxiety neurotics, controls and "scared soldiers" was made to corroborate our impression that ordinarily our group represents a normal or control sample but that with stress of upcoming exams it shifted toward that of the "scared soldiers." The qualitative and quantitative differences between threat of combat and medical school examination account for the discrepancies in incidence of certain of the symptoms reported.

The difference between the configuration of symptoms of anxiety neurosis and those seen as a response to the stress of examina-

tion should not be neglected. It has been suggested that each attitude is intimately connected with a group of specific physiological responses and evidence may be adduced to support this contention (11, 12). Just as it would be expected that sexual stimuli would produce different physiological responses than a death in the family or the joy over a fortuitous event, so might it be expected that the stress of examination would be associated with quite different attitudes and physiological responses than those seen in a paratrooper ready to jump out of a plane (the "scared soldiers") or a patient with anxiety neurosis. There is clearly an area of overlap but there is also an area of differentiation. Sexual excitement in the male, for example, is associated with rapid pulse and increased respiratory rate as well as genital changes, whereas anxiety neurosis is characterized by the presence of the first two of these symptoms but not of the third.

Utilizing our own data as well as those of the White and Cohen study on anxiety neurosis and "scared soldiers" we note a marked increase in the incidence of dyspnea, dizziness, faintness, chest pain, headache and syncope in the patients with anxiety neurosis as opposed to those subjects responding to examination or the "scared soldiers." The differentiation between the "scared soldiers" and the students responding to examination is less striking but there appear to be differences in palpitations, weakness, trembling and G.I. symptoms.

The high incidence of symptoms commonly considered of psychiatric import such as dreams, nightmares, syncope, hallucinations, phobias, obsessions, compulsions, and suicidal thoughts was tabulated to substantiate their ubiquitous nature and to re-emphasize that it is the quality of the symptom rather than the occurrence which indicates psychiatric illness. The use of alcohol was of high incidence but of little importance to all but one of this relatively young population. Twenty percent of the subjects used large doses of caffeine or dextro-drine when studying for exams, but at no other times; such ingestion could account for some of the "anxiety" symptoms at these periods but most subjects reported the same symptoms with or without their ingestion.

CONCLUSIONS

1. A random sample of 40 sophomore medical students out of 80 was given structured psychiatric interviews.

2. Six (15%) of the group were psychiatrically ill; of these 3 were manic-depressives, one an anxiety neurotic, one a chronic alcoholic, and one ill but undiagnosed.

3. The psychiatrically ill subjects had an incidence of positive family history of psychiatric illness that was markedly greater than that of the well subjects; this difference was statistically significant to the 0.0001 level. In addition, the ill relatives of ill subjects were not only genetically much closer than those of the well subjects but appeared to suffer different illnesses.

4. Anxiety symptoms did not increase in pre-exam periods in the psychiatrically ill; but those of well subjects, previously quite different, approached those of the ill in pre-exam periods.

5. Anxiety ratings in ordinary circumstances do not correlate with those of pre-exam periods for the group.

6. In ordinary circumstances our group resembled a control population rather than anxiety neurotics in terms of incidence of anxiety symptoms. In pre-exam periods the group resembled the "scared soldiers" reported by Cohen, White, *et al.* Differences, however, were present.

7. The incidence of psychiatric symptoms such as dreams, nightmares, hallucinations, suicidal thoughts, and phobias was quite high in our subjects but the quality of such symptoms was innocuous in all but the 6 ill subjects.

THE PSYCHIATRIC PATIENT AS HIS OWN HISTORIAN

JAMES A. KENNY,¹ AND RONALD C. BOUNOUS²

In these days of advanced techniques, psychiatric examiners have gone beyond a patient's verbalizations in their search for material of diagnostic importance. Various other means of self-expression have been tapped, such as drawing, playing, and singing. We feel that the patient's writing, when adequately focused and thoughtfully studied, can yield fruitful data for diagnosis. We have special interest in forms for gathering social history information.

But when would a social worker use a form to gather social history data? Is not one of the main techniques and skills of a social worker his interviewing ability?

This reaction is somewhat typical, and it has prevented social workers from developing good history questionnaires. In this article we hope to present the pros and cons of using such questionnaires. Further, we will include many of the questions we have used in our various history-gathering questionnaires with the hope that our experience will stimulate professional interest in this tool or technique. Psychiatrists in private practice have used social history forms in an effort to save their own time and the patient's money. An inadequate questionnaire is certainly of limited value and could possibly be harmful to later psychotherapy.

Our social history questionnaire came out of the need to handle a heavy work load with a minimum of fully trained personnel. The authors worked for 2½ years in the psychiatric department of a military hospital with about 120 full patient beds (average patient stay was about 45 days). We also participated in a fairly large outpatient psychiatric clinic. The professional staff consisted of 9 psychiatrists, 2 psychologists, and 2 social workers. In the social work section we had approximately 4 partially trained technicians. A complete diagnostic evaluation and disposition was the main focus of our inpatient psychiatric facility. A detailed

and accurate social history was of prime importance in fully evaluating our military patients. Many members of our professional staff were frankly skeptical that a social history questionnaire would be of any value. Therefore, our present questionnaires have undergone a "baptism through fire" in staff discussions and in trial and error use with our patients and their relatives for over 2 years.

Prior to going into the more concrete aspects of our pro and con discussion we will briefly attempt to answer our main introductory question. If social workers and psychiatrists are frequently opposed to questionnaires, as our recent experiences have shown, we must ask why. Among the many possible answers we have found are that the therapeutic orientation of social workers combined with their rather arduous training in sensitive diagnostic interviewing may predispose their using only the tools with which they are most familiar. Thus when called upon to fill their role in a diagnostic setting, they are sometimes prone to slow things down with long and careful explorations. We believe that this, unfortunately, means that they are missing an opportunity to better use their time, which leads into the first and probably most important of our "pro" arguments.

PRO SOCIAL HISTORY QUESTIONNAIRE

1. We believe that social history questionnaires save time. Where time is an important factor this advantage may be of critical importance. Many of us have had to establish treatment priorities from referrals with a history gleaned from a brief half hour or hour contact with the patient or his relative. Frequently, it is only possible to obtain factual information, or perhaps, a hurried and anxious explanation of what is considered to be the most pressing problem. This is operating under quite a disadvantage, but it is a situation with which most of us are very familiar. We have developed a high degree of sensitivity to the subtleties of the human personality and the interview-

¹ Chief Psychiatric Social Worker, U.S.A.F. Hospital, Wiesbaden, Germany.

² Chief Psychiatric Social Worker, Eglin Air Force Base Hospital, Fla.

ing process in order to make the best use of our time.

We have found that the social history questionnaire can serve as a good starting point for a detailed life history or it can add a valuable perspective to the patient's immediate problems. The time saved by using a questionnaire can be used to see more patients or more thoroughly evaluate those we are presently seeing.

2. The questionnaire offers a standardized method for gaining prime material. Familiarity with the form and the comparison of numerous responses enables the worker to gain a wealth of information aside from the factual answers. Just as an interview has the added features of non-verbal communication, gestures, tone, expressions, blocking ; so a written document has its erasures, pressures, omissions, evasions, and completion time(6). Much of this material can be further explored by the worker in the follow-up interview.

3. Good questionnaires have a built-in supervisory feature. This is especially important in the military where one makes extensive use of social work technicians. They give the technician a structured base for interviewing some patients. They also give the supervision and added control, because dynamic personality variables can readily be postulated from the factual questionnaire information. One can be assured of a history with a certain comprehensiveness and quality.

4. Life history forms may keep patients constructively occupied. Where patients are hospitalized with little to keep them busy for long periods of time, or where agency waiting lists are long, this can be a therapeutic boon. On occasion we have asked selected patients to write a lengthy and detailed autobiography using the questionnaire as an outline.

5. Finally, there is the pragmatic argument that social history questionnaires *are* and *will be* used in some situations where time and personnel are limited. So we might just as well work to develop good ones.

these can be modified. The two main objections are : 1. They are impersonal. 2. They are superficial. 3. Some felt that the questionnaires have patterned the patient's responses in a rigid, stereotypical fashion and thereby destroyed the spontaneity of later history-taking. There is a danger in writing something down that some persons will feel what they have written becomes irrevocably affirmed. 4. It was also believed by some that this rigidity could damage later therapeutic attempts. 5. Finally, a few felt that history questionnaires helped a patient prepare for psychological testing in such a way that he was better able to mask his personality symptoms.

All of these arguments have some validity. However, we have found that we can greatly diminish the impersonal and superficial nature of the questionnaire by a sensitive, personable introduction and administration, and by a good follow-up interview by the historian. Further, our psychologists have tested 90% of all the patients that have received the questionnaire and have reported no deleterious patterning or rigidity that could be attributed to the questionnaire. We have found that patients having a paranoid or a passive aggressive diagnosis tended to give bare factual information. These same patients occasionally refused to answer the questionnaire. While this is a limitation, here again the productivity of the instrument can be raised by anticipating this problem and correcting for it in a good introductory and follow-up interview.

The very impersonality of a form can be an advantage in certain cases. Where the patient is fearful of interpersonal contact, the objectivity of a form may provide a less threatening medium for self-expression. This however, is more the exception than the rule. Finally, it should be noted that the history questionnaire is not meant to replace the psychiatric interview wherein the here-and-now of adjustment and personality dynamics are probed. Rather the questionnaire is mainly intended to supply factual background information with as much feeling tone as can be coaxed from a patient by a form.

THE ARGUMENTS AGAINST SOCIAL HISTORY QUESTIONNAIRES

Of course, the use of history questionnaires has its negative features. Some of

DEVELOPMENT

The first step in the development of tech-

nique is a study of the purpose for which the technique is intended. Our purpose was diagnostic. Could the men be retained in the military? If not, under what provisions and with what benefits ought they to be discharged? The questionnaire must help fulfill the purpose of the hospital or clinic. Thus an all-purpose history questionnaire would probably be undesirable. The questions contained might differ from clinic to clinic, from year to year, dependent always on the purpose.

Our next step was to review the literature (1, 2, 3, 4, 5). We also wrote to a number of state hospitals and many agencies for copies of their forms. Then we gathered all the questions we thought might prove useful and administered them to a group of about 20 patients having mixed diagnoses. We modified the questionnaire and again administered it.

Our questionnaire has developed into its present state through 4 major revisions over a period of 3 years. To encourage informality we have attempted to keep a conversational tone throughout, and have entirely eliminated the purely projective questions found in our earlier versions. Further, we have noted the trend through our revisions to ask more specific questions and request more specific answers. This counteracts an earlier tendency to ask several stimulating questions in a group and then leave a space open for a discussion of the life area concerned, *e.g.*, parents, marriage, job. It was found that in this latter case, patients would avoid certain problem questions.

We call our social history questionnaire the SASH (Self-Administered Social History). In its present version it is 12 pages long with space left for answers. It is given in conjunction with a military medical history form, and we feel that we have had excellent results. We have given approximately 500 and know of no situations where it has caused any difficulties; there were less than 10 instances where cooperation was lacking to an extent to make the SASH worthless.

Later we modified the SASH for use with relatives where direct contact was impossible. In the good military tradition of abbreviation we called this modified version SQUARE (Social Questionnaire An-

swered by Relatives). The SQUARE is composed of 8 pages, but there is no accompanying medical history form. Again the results have proven gratifying. Using stamped return envelopes we have received a surprising 90% plus return on over 300 SQUAREs mailed out. The data returned were richer in quality and more extensive in quantity than what we had been receiving in the SASH. No doubt this was due to the fact that it was easier for one person to report on another. The SQUARE is presently undergoing a thorough item analysis and will be reported on later.

SUMMARY

The social history questionnaire is not a substitute for, nor can it be favorably compared to history-taking in a personal interview. Yet we feel that it is a legitimate diagnostic instrument in certain situations. That is to say, the questionnaire is preferable to sparse information gathered in a hasty manner or to no history at all. The time it saves, the prime material it offers, its built-in supervisory features, and its therapeutic possibilities may counterbalance the impersonality and superficiality of a form. We are presenting our SASH (Self-Administered Social History) in the hope that others will do likewise, and that certain optimum history questionnaires and questions might be developed.

APPENDIX

ADMINISTRATION

The SASH begins with a brief written explanatory introduction.

"The purpose of this form is to obtain a history of your earlier life. The information you are able to give will aid us in coming to a better understanding of you and your problems. Some of these questions may not apply to you. Others may be hard to answer. You will have to think about them. Take your time. Try to answer each question as accurately as possible."

The person administering the SASH spends approximately 10 minutes establishing a relationship and expanding on this introduction. For example, we might compare the SASH to an autobiography. Then the patient is left to complete the questionnaire. Ordinarily this takes from 45 minutes to 2 hours. When the patient has finished, the administrator goes

through the SASH with him and makes any clarifying additions in red pencil. This usually requires 5 to 10 minutes. When necessary, the SASH can be administered to groups, providing patients have a certain privacy in filling out the forms. We found that it was not a good idea to let the patients return to the psychiatric wards with the SASH. They usually produced less when filling out the SASH in the proximity of their wardmates.

SASH

The SASH begins with the usual identifying data. We have omitted these in the present article. However, we felt the questions we developed in the SASH might prove interesting to others. So we have reported them in full. In the actual questionnaire, sufficient room was left between the questions for the patient's written answers.

MEDICAL HISTORY

1. Tell us about your problem(s). Explain why you are in the hospital.
2. Have you ever needed or received medical care for a nervous breakdown, nervousness, emotional upset, worrying, or extreme sadness? Dates—Place—Type of Treatment and Condition.

MILITARY HISTORY

1. Describe briefly your military career. (If female, describe husband's military career since marriage). Dates—Base—Type of Duty.
2. Where did you enter service?—Why did you enter service?
3. What tour of duty did you like best? Why?
4. Tell us about any ribbons, letters of commendation, or decorations which you have been awarded. Have you ever lost rank, had a court-martial, or received an Article 15? Explain. Date—Award or Punishment—Reason.

FAMILY HISTORY

1. Father's age—Year parents married—.
2. Father's education (grade completed and year)—.
3. Father's job—Average salary—.
4. Tell us about your father, what kind of a man was he? Describe him. (Include habits, such as drinking, smoking or using drugs.)
5. What did your father do for recreation and relaxation?
6. Mention your father's attitudes toward religion.
7. Mother's age—Mother's education (grade completed and year)—.

8. Did your mother work? Years—Type of Job—Reason for working.

9. Tell us about your mother, what kind of woman was she? Describe her. (Include habits, such as drinking, smoking or using drugs.)

10. Mention your mother's attitudes toward religion.

11. What did your mother do for recreation and relaxation?

12. What nationality were your parents? Father—Mother—. Was a foreign language spoken in your home? What was it?

13. Name any step-parents or persons who took care of you as a child. Tell us how old you were then. Describe these persons.

14. Explain here any separations of your parents due to divorce, illness, death, etc. Give the year and reason.

15. When you were growing up, who disciplined the children in your family? How was it done? Give examples.

16. How did your parents solve family problems and differences? Please give an example.

17. Who handled the family bills, rent, food, car, etc.?

18. Tell us about your brothers and sisters. Names—Age—Marital Status—Occupation—If Deceased Give Year and Cause of Death.

19. Which brother or sister do you write or visit most often? Why?

20. With which brother or sister did you have the most problems?

21. With which brother or sister did you get along best? Why?

22. Who else lived with you besides your parents, brothers and sisters? How old were you then?

How did they get along with the family and how did you get along with them?

23. Have any family members had an emotional illness or a nervous breakdown? Explain.

24. Have any of your family members been severely injured or suffered from a physical handicap? Name—Relationship—Date—Type of Illness and Treatment.

CHILDHOOD

1. What kind of neighborhood(s) did you grow up in? Tell us what you thought of it (them).

2. About how many children were there around for you to play with *before* you went to school? What games do you remember playing at that time?

3. How would you describe yourself as a child? (quiet, active, shy, nervous, etc.).

4. Did you change while growing up?

Please tell us how old you were and why you changed.

5. Tell us about the games you played during grade school.

6. About how often did your family attend church?

7. What was the size of the town(s) in which you were raised?

8. If you lived in more than one town, which one did you like best? Why?

9. How many different houses did your family live in before you were 15 years old?

10. As a child, did you have a temper? What sort of things made you angry?

11. Did you cry much as a child? When you were in grade school, what things made you cry?

SCHOOL HISTORY

1. Tell us when and where you attended school from the first grade to the present. Dates—Name of School—City and State.

2. What kinds of marks did you get in school? (excellent, good, average, fair, poor). Grade school—, Junior High—, High School—, College or Technical School—.

3. Tell us about any special classes in which you have been, any grades you have repeated, or any grades you have skipped. Explain.

4. Describe your schooling and education. Mention any favorite teachers. Tell us your favorite subjects; also any subjects you had trouble with or did not like:

- a. Grammar School (grade and junior high)
- b. High School
- c. College or Technical School

5. List the extracurricular activities that you were in (sports, music, clubs).

6. What did you like about school?

7. What did you dislike about school?

8. Why did you leave school? What were your plans?

DATING AND MARRIAGE

1. How old were you when you began dating?

2. Tell us about your first date. Did you go alone? Where did you go? What did you do?

3. How frequently did you date as a teenager?

4. What did you like to do on a date?

5. Tell us what type of woman (man) you prefer.

6. Did you usually date women (men) who were younger, the same age, or older than you?

7. Tell us how you learned about sexual intercourse. When? From whom?

8. Tell us about your present marriage. Describe your spouse.

9. How long had you known her (him)—and when did you marry?

10. What do you enjoy most about your marriage?

11. Who handles the finances? (paying rent, food, car, etc.) Are there ever any difficulties over the arrangement? Explain.

12. What adjustments did you make after marriage?

13. Tell us about your children. Name—Birthdate—Sex—Grade in School or Occupation—Marital Status.

14. Have your children ever had any serious accidents or illnesses? Name—Date, Condition or Injury—Treatment or Outcome.

15. Which child seems to be the easiest to get along with? Why?

16. Which child seems to be the most difficult to get along with? Why?

17. Who disciplines the children? How is it done?

18. Have you ever lost any children through miscarriage or death? Please give dates and explain.

19. Tell us about any previous marriages. Date of marriage—and divorce.

20. Reasons for divorce.

21. Please list the name, age, and sex of any children of previous marriages.

JOB HISTORY

1. Tell us about the first job you had for which you got paid. What did you do with the money?

2. What was your usual civilian occupation?

3. What is your usual job in service?

4. Were the people on your last (or present) job easy to get along with? Please explain any problems with either the people or the type of work on your last job.

5. If you had a choice what kind of job would you like to have? Why?

6. Tell us about the jobs you held in civilian life. Dates—Type of work—Salary—Reason for Leaving.

PERSONAL ATTITUDES AND RECREATION

1. Tell us about any clubs or organizations that you belong to or have belonged to. Date—Name of Club or Organization—Offices held.

2. Tell us what you like to do for recreation.

3. Mention your attitude toward religion. Do you believe in God? How often do you pray, attend church? Explain.

4. Tell us about your personal habits, such as drinking, smoking, and using drugs. Mention when you started, why, and how much you drink, smoke, or use drugs now.

5. Mention any foods that disagree with you. Do you have any allergies?

6. Mention any trouble that you have been in with the law. Date—Place—Offense—Outcome.

7. Where would you go and what would you do if you were to be discharged from the service?

8. Has your present hospitalization created any problems in your family? Explain.

9. Tell us anything else that you have not mentioned about your feelings, friends, or life history that you believe is important.

CLINICAL NOTES

(The Clinical Notes report the findings of the authors and do not necessarily represent the opinions of the Journal.)

A "DOUBLE BLIND" STUDY COMPARING RO 4-0403, TRIFLUOPERAZINE AND A PLACEBO IN CHRONICALLY ILL MENTAL PATIENTS¹

ANTIOCO BARRON, M.D., BARBARA BECKERING, R.N.,
LESTER H. RUDY, M.D., AND JACKSON A. SMITH, M.D.²

As the flow of new psychotropic drugs continues a comparison of these new products with established therapeutic agents is one method of evaluating their potential. The following "Double Blind" study compares a new drug RO 4-0403 (Taractan) with Trifluoperazine (Stelazine),³ an extensively used compound, and a placebo.

Thirty chronic female patients from a continuous treatment ward in a large state hospital, selected because of their aggressive or agitated behavior and the chronicity of their illness, composed the patient group. Their ages ranged from 22 to 60 years. All had been hospitalized for a year or longer with an average of 10.5 years (10 patients over 15 years). Twenty-four were diagnosed as schizophrenics and 6 were considered to be involutional psychotics.

The project was carried out as a "double blind" with a cross over. The patients were randomly selected and divided into 3 groups of 10 each, designated A, B and C; similarly preparation A was RO 4-0403 (Taractan),

was a placebo.

The groups received each preparation for a period of 1 month with weekly increases of dosage. The "cross over" was done at the end of each month and all 3 groups received each preparation for a 30-day period. Due to the disturbed state of the patients, only 48 to 72 hours was allowed to elapse between drugs. The two medications and the placebo were prepared in identical capsules. Neither the patients nor the observer were aware which medication was being given.

A research nurse, who was an experienced observer, utilized standardized evaluation forms previously described⁴ to record any change in the patients' behavior. She had been in contact with this group of patients and was familiar with their reaction patterns and behavior on and off the ward. In addition to weekly progress notes she made a complete control evaluation of each patient immediately prior to the start of the project and at the end of each month. A psychiatrist worked with her and evaluated side effects from the drugs: complete blood counts and liver function tests (alkaline phosphatase and thymol turbidity) were done weekly throughout the length of the study.

¹ This study was done at the Chicago State Hospital and the cooperation of Dr. H. Matlz, Superintendent, is appreciated.

² Staff of the Illinois State Psychiatric Institute, Chicago, Illinois.

³ Appreciation is expressed to the Smith Kline and French Laboratories for the supplies of trifluoperazine (Stelazine), and to Hoffmann-La Roche Inc. for RO 4-0403 (Taractan).
B was trifluoperazine (Stelazine) and C

⁴ Smith, Jackson A., Christian, Dorothy, Mansfield, Elaine, and Figaredo, Alfredo: *Am. J. Psychiat.*, 116: 392, Nov. 1959.

Dosage and Administration

	RO 4-0403	Trifluoperazine	Placebo
1st week	75 mg. daily	6 mg. daily	—
2nd week	150 mg. daily	10 mg. daily	—
3rd week	300 mg. daily	10 mg. daily	—
4th week	600 mg. daily	20 mg. daily	—

RESULTS

The patient's clinical response during the study was tabulated and the final results are shown in the following table :

	Worse	Change	Slightly Improved	Moderately Improved	Markedly Improved
Drug A (Taractan)	10	13	7	0	0
Drug B (Stelazine)	0	11	12	7	0
Drug C (Placebo)	13	16	1	0	0

The criteria used for evaluation was derived from observing a decrease or increase in the following variables of behavior : over hostility, tension, agitation, attempts to communicate, cooperation, friendliness, attention span and alertness, interest in personal appearance, mannerisms, participation in activities or a change in delusions and hallucinations. Patients considered slightly improved showed favorable change in 2 or 3 variables. Moderately improved patients showed this change in at least 4 or 5 variables. Marked improvement reflected change in 6 or more of the listed variables. No patient was considered markedly improved and a patient was considered worse if an unfavorable change was noted in 2 or more of the variables.

SIDE EFFECTS

No serious side effects were encountered with either of the 2 active drugs used. The following mild side effects were observed :

	Tremor and mild muscular rigidity	Drooping & Mask-like facies	Short period of increased agitation
Drug A (Taractan)	1	1	0
Drug B (Stelazine)	8	1	3
Drug C (Placebo)	0	0	0

The observed side effects with both active drugs were controllable with anti-Parkinsonian medication.

CONCLUSIONS

1. RO 4-0403 (Taractan) produced a beneficial response in 7 of a group of 30 extremely chronic psychotic patients. Those

patients who responded showed a decrease in agitation, appeared more friendly and expressed the subjective sensation of "feeling better." Undesirable side effects were observed in only 2 of the 30 patients treated. From these results it would appear that this compound can be safely and effectively used in acute psychiatric disorders.

2. Trifluoperazine (Stelazine) is a potent drug that is effective in reducing the symptomatology in chronic psychotic patients. In this study more than half the patients who received trifluoperazine showed a desirable change of behavior during the study but side effects were noted in 40% of those treated. These side effects usually appeared at a high dosage and disappeared promptly after the administration of anti-Parkinsonian drugs.

3. Since only 1 patient out of 30 showed a slight improvement while receiving a placebo, it is presumed that suggestion and

attention were of minimal importance in producing the changes observed with the active compounds.

CLINICAL OBSERVATIONS OF THERAPEUTIC EFFECT OF CHLORPROTHIXENE (TARACTAN) IN PSYCHOSES

LEON REZNIKOFF, M.D.¹

Reports appeared recently in psychiatric literature of therapeutic value of a new psy-

chopharmacological agent, chlorprothixene,² attributing to it both tranquilizing and anti-

¹ Clinical Director, Hudson County Hospital for Mental Diseases, Secaucus, N. J.

² Chlorprothixene was supplied by Hoffmann-LaRoche Laboratories, under trade name, Taractan.

depressant properties. Chlorprothixene has a chemical formula similar to chlorpromazine, except that nitrogen in the phenothiazine ring is replaced by unsaturated carbon atom.

The present report deals with observations made during the use of chlorprothixene for 2 to 8 months in 60 hospitalized psychotic patients. The following diagnostic categories were represented: schizophrenic reaction—50 patients; manic-depressive, depressed type—7 patients; mental deficiency with psychotic reaction—2; sociopathic personality with psychotic reaction—1.

Schizophrenic patients were subdivided into following types: paranoid 35, catatonic 5, hebephrenic 4, simple 1, and chronic undifferentiated type, 5.

The average duration of schizophrenic psychosis was about 6 years. Most of the patients had been previously treated with ECT and different phenothiazine drugs, but either failed to maintain improvement or did not improve at all.

Chlorprothixene was administered orally. The initial dose of 25 mg. b.i.d. was gradually increased to 200 mg. to 300 mg. b.i.d.; only 6 patients received maximum dosage of 600 mg. per day; in most cases 150 mg. to 200 mg. b.i.d. was sufficient. After what appeared to be maximum improvement the dosage was gradually reduced to a maintenance of 25 mg. or 50 mg. per day.

There were no cases of agranulocytosis, jaundice or skin rash. Transaminase tests, urinalysis and frequent blood counts were carried out in all patients, and showed no significant changes. There was no marked change in weight. Two patients had moderate hypotension, and when a third developed marked hypotension, the drug was discontinued for 2 days and then resumed at half dosage; his blood pressure returned to normal. Four complained of dizziness, but were able to continue with the therapy. Two developed mild extrapyramidal symptoms which had been easily controlled by Akineton. In no case had treatment to be discontinued because of side effects.

Chlorprothixene apparently produces tranquilizing and sedative effects in anxious and agitated patients, and also has antidepressant effect on apathetic and depressed patients. Generally improvement had been

gradual; no dramatic results had been observed.

Of the 50 schizophrenics 20 (40%) improved sufficiently to be released for convalescent care; another 13 (26%) made a fairly good institutional adjustment and began to participate in occupational and recreational activities; 17 (34%) showed only slight, or transient improvement and therefore classified as unimproved.

The results in non-schizophrenic patients were as follows: of the 7 manic-depressive, depressed patients 4 achieved remission, the other 3 were unimproved; the 2 mentally deficient patients with psychotic reaction became free of psychosis; the sociopath with psychotic reaction also recovered from psychosis after a few weeks on chlorprothixene. Four uncooperative schizophrenic patients and one manic-depressive, depressed had to be placed on ECT after a trial with chlorprothixene was unsuccessful.

The small number of psychotic depressions is not sufficient for statistical evaluation; however, it is our impression that it is not a drug of choice for treatment of deep psychotic depressions, since better results are obtained with ECT, MAO inhibitors, or imipramine.

SUMMARY AND CONCLUSIONS

Sixty psychotic patients have been treated with chlorprothixene for 8 to 32 weeks; most of the patients were chronic schizophrenics. Twenty (40%) schizophrenics improved or achieved a remission to be released for convalescent care; 13 (26%) improved sufficiently to participate in hospital social, occupational and recreational activities and 17 (34%) remained unimproved. The number of non-schizophrenic patients was too small to be statistically significant. Frequent blood counts and transaminase studies revealed no significant abnormalities; there were no cases of agranulocytosis, jaundice or skin rash; mild extrapyramidal symptoms developed in 2 patients, but were easily controlled with Akineton, and did not require discontinuation of chlorprothixene.

Both tranquilizing and antidepressant effects are gradual; no dramatic changes have been observed.

Chlorprothixene might be useful in treat-

ment of schizophrenic patients who have some depressive features, or become de-

pressed from large doses of other tranquilizers.

WITHDRAWAL OF MAINTENANCE ANTIPARKINSON DRUG IN THE PHENOTHIAZINE-INDUCED EXTRAPYRAMIDAL REACTION

WILLIAM MANDEL, M.D., AND W. A. OLIVER, M.D.¹

This study was conducted to obtain data concerning the recurrence rate of phenothiazine-induced extrapyramidal reactions following withdrawal of maintenance antiparkinson drug.

Sixty-three chronic schizophrenic patients from 5 continuous treatment wards comprised the patient sample. These patients were each receiving a phenothiazine² as well as a maintenance antiparkinson drug; the antiparkinson drug having been given for the control of phenothiazine-induced extrapyramidal reactions. A placebo and triphenidyl,³ the identity being unknown to patients and personnel, were randomly assigned to the patient population so that 2 out of 3 patients (41 patients) received the placebo and the third patient (22 patients) received triphenidyl. The unknown medications were abruptly substituted for the maintenance antiparkinson drug in dosages of 1 tablet t.i.d. (6 mg. of triphenidyl). Prior to the start and at frequent intervals during the study, the patients were assessed for clinical manifestations of the extrapyramidal reaction. When such manifestations recurred, the dosages of the unknowns were increased to 2 tablets t.i.d. (12 mg. of triphenidyl); if the reaction became more severe, the unknowns were discontinued and replaced with the previous maintenance antiparkinson drug. The duration of the study on the 5 wards ranged from 28 to 38 days, the mean being 34 days.⁴

RESULTS

Replacement of the unknown medication by the previous maintenance dosage of antiparkinson drug was not required in 24 of the 41 placebo-treated patients (59%) and in 21 of the 22 triphenidyl-treated patients. Clinical manifestations of the extrapyramidal reaction were controlled in the 18 patients in whom the unknowns were replaced by the previous maintenance antiparkinson drug.

DISCUSSION

The recurrence rate in the thioperazine-induced extrapyramidal reaction following placebo substitution for maintenance antiparkinson drug was reported (1) to be 80%. Thioperazine is a phenothiazine derivative which produces a rapid onset and high incidence of extrapyramidal reactions. These results are in contrast to a report (2) of a 21% recurrence in patients treated for chlorpromazine- and reserpine-induced extrapyramidal reactions. In this present study, the recurrence rate in phenothiazine-induced reactions following placebo substitution for maintenance antiparkinson drug was 41%. These differences are the result of the many variables in the study situations.

Depending on the clinical situation, maintenance antiparkinson drug is not required to prevent recurrence of clinical manifestations of phenothiazine-induced extrapyramidal reactions in from 20 to 80% of patients. Trials are recommended in which maintenance antiparkinson drugs are withdrawn and antiparkinson treatment restarted

¹ Respectively, Chief of Research, and Associate Superintendent, Napa State Hospital, Imola, California.

² The five phenothiazine derivatives were: chlorpromazine, fluphenazine, perphenazine, prochlorperazine, and trifluoperazine.

³ Placebo and triphenidyl (Artane) were supplied by Dr. William Sweeney, Lederle Laboratories.

⁴ Data on the age and sex of the patients, the

phenothiazine and maintenance antiparkinson drug and dosages, the length of prior treatment with these drugs, the days on which the unknown medications were increased to 2 tablets t.i.d. and were discontinued, are available on request.

only in those instances in which clinical manifestations of extrapyramidal reactions recur.

SUMMARY

A placebo was substituted for maintenance antiparkinson drug in 41 patients who had been given this medication for the control of phenothiazine-induced extra-pyramidal reactions. These reactions did not recur in 24 of the 41 patients (59%). Although recurrence rates will vary with different clinical situations, it is probable that a large

proportion of patients do not require maintenance antiparkinson drug for continued clinical control of phenothiazine-induced extra-pyramidal reactions. Trials are recommended to determine which patients should or should not continue to receive maintenance antiparkinson drug.

RECURRENT THIOPERAZINE-INDUCED EXTRAPYRAMIDAL REACTION FOLLOWING PLACEBO SUBSTITUTION FOR MAINTENANCE ANTIPARKINSON DRUG

WILLIAM MANDEL, M.D., BESSIE CLAFFEY, M.D., AND
LESTER H. MARGOLIS, M.D.¹

This report describes the incidence and time of recurrence of the thioperazine-induced extrapyramidal reaction in 20 patients in whom placebos were substituted for maintenance antiparkinson drug. The results were obtained during a study in which a new antiparkinson drug (UK-738)² was evaluated.

MATERIALS AND METHODS

Forty chronic schizophrenic patients, 20 men and 20 women, receiving thioperazine² in sufficient dosage to produce extrapyramidal reactions and who were maintained on antiparkinson drug (triphenidyl) to control this phenothiazine-induced reaction were studied. All patients received thioperazine for 4 months and triphenidyl² for at least 3 months. The range of thioperazine daily dose was 4 mg. to 120 mg. (mean—31 mg.). The range of triphenidyl daily dose was 5 mg. to 20 mg. (mean—13 mg.). Ages of patients ranged from 18 to 59 years (mean—41).

¹ Respectively, Chief of Research, Staff Psychiatrist, and Consultant, Napa State Hospital, Imola, Calif.

² UK-738 (N-ethyl-nortropine-benzhydrylether-hydrobromide) supplied by Sandoz Pharmaceuticals; thioperazine supplied by Ives-Cameron Company; triphenidyl (Artane) supplied by Lederle Laboratories.

A placebo and UK-738 were randomly assigned so that 10 men and 10 women received each preparation; the study was double-blind. Each patient was first clinically assessed for extra-pyramidal symptoms and signs. With the thioperazine dosage kept constant, the unknowns were abruptly substituted for triphenidyl in a dosage of one tablet t.i.d. Reassessments for extra-pyramidal reactions were performed daily. When symptoms recurred and were marked, the unknowns were replaced with the previous triphenidyl dosage; if symptoms recurred and were not as marked, dosages of the unknowns were increased to 2 tablets t.i.d. The study was concluded after 20 days.

RESULTS

Within 20 days, the 10 women and 6 of the 10 men (80%), in whom placebos were substituted for triphenidyl developed sufficiently marked recurrence of extrapyramidal reactions to necessitate resumption of their triphenidyl dosage. At the completion of the investigation, 3 of the 4 men were still receiving placebo, one tablet t.i.d., while the fourth was receiving 2 tablets of placebo t.i.d. In 4 of the 10 women, the recurrent reaction was so marked that the placebo was discontinued without prior in-

crease in dosage; the remaining 6 women and the 6 men had a more gradual recurrence and were first tried with 2 placebo tablets t.i.d. The time of discontinuation of placebo and return to triphenidyl is shown in Table I. Table II shows the time when

TABLE I

Men (6)	3		3	

the placebo was increased to 2 tablets t.i.d. By the fourth study day, the placebo had been discontinued in 5 patients and 7 patients were receiving 2 tablets t.i.d.; thus, 12 of 16 patients in whom the placebo was discontinued had recurrence in 4 days. The recurrent reactions were controlled with resumption of triphenidyl.

DISCUSSION

Despite many reports dealing with phenothiazine-induced extrapyramidal reactions, few have described the recurrence rate when maintenance antiparkinson drug was

stopped. Cahan and Parrish(1) reported recurrence in the chlorpromazine- and reserpine-induced parkinson syndrome after discontinuing antiparkinson drug in 17 of 83 patients (21%) stating, "the majority of patients with drug-induced parkinsonism, after a period, no longer need the antiparkinson drug they are receiving." Their results differ from ours but single studies cannot set limits for the universe of patients nor for many treatment situations, e.g., thioperazine is a phenothiazine which produces a rapid onset and high incidence of extrapyramidal reactions(2). Recurrence in specific situations can only be determined by clinical trials; such trials should clarify the relative need for maintenance antiparkinson drug in phenothiazine-treated patients.

SUMMARY

A placebo was abruptly substituted for maintenance antiparkinson drug in 20 patients who had previously shown evidence of a thioperazine-induced extrapyramidal reaction. Within 20 days of this controlled study extrapyramidal reactions reappeared in 16 patients (80%). The recurrence rate of phenothiazine-induced extrapyramidal reactions following withdrawal of maintenance antiparkinson drug will vary with different situations and their incidence can only be determined by clinical trial.

TRANLYCYPROMINE AND TRIFLUOPERAZINE IN THE TREATMENT OF DANGEROUS HOSPITALIZED PATIENTS

ANTHONY LAPOLLA, M.D.¹

Thirty-one adult criminally insane male patients at Atascadero State Hospital (a maximum security hospital) who required close custody because of aggressive or com-

bative behavior were treated with tablets containing 10 mg. tranlycypromine, an anti-depressant, and 2 mg. trifluoperazine, a tranquilizer, for 3 months. These men, age range 23 to 65 years (average: 40 years), had been hospitalized for an average of over 2 years, and had not responded adequately

¹ Louis R. Nash, M.D., Acting Superintendent and Medical Director of the Atascadero State Hospital.

to previous therapy with various phenothiazine drugs, including trifluoperazine alone. Diagnoses varied (see Table 1) but all

ease (mitral insufficiency), suffered a heart failure and died during the eighth week of the evaluation but there was no evidence

^a Patient died after course of ECT during eighth week of evaluation.

were depressed or presented evidence of withdrawal and marked asocial behavior. Initial dosage for all patients was one tablet at breakfast and one at 4:00 p.m. All patients were observed daily by the technical staff and the ward physician and staff meetings were held every 15 days to review and discuss the progress of each patient, and to decide whether changes in dosage should be made or additional therapeutic measures introduced. In 8 patients who did not respond, and 12 who showed only marginal improvement after 2-4 weeks of therapy, the dosage was increased to 2 tablets, b.i.d. While no other psychopharmaceuticals were used, 9 patients also received electroshock therapy 6 weeks to 2 months after the study began.

At the completion of the study, 5 patients (one had received concomitant ECT) were markedly improved, i.e., complete remission of psychotic and depressive symptoms; 14 (2 had received concomitant ECT) were moderately improved, i.e., significant but incomplete remission of symptoms; 5 were slightly improved; and 7 (6 had received concomitant ECT) were not improved at all. Results by diagnosis are shown in Table 1. One of the patients who received ECT, a 32-year-old patient with catatonic schizophrenia who also had a cardiovascular dis-

ease (mitral insufficiency) or liver damage) in him or in any patient.

Although these patients had a history of aggressive and/or combative behavior, there was no acting out of symptoms, no increase in aggressive behavior, and no combative behavior appeared. The substantial improvement in 19 (61%) of these patients whose symptoms had been present for many months and who had not responded to previous therapy was surprising—particularly in view of the short duration of the study and limited doses used. However, while it is probable that beneficial changes would have occurred in more patients had we increased the dosage, it is probable that the incidence of side effects would have increased too.

As it was, side effects were reported by 10 patients. Transient insomnia or jitters was reported by 3 patients at a dosage of one tablet b.i.d., and by 6 at a dosage of 2 tablets b.i.d. These symptoms disappeared as treatment continued and no changes in dosage were necessary. One other patient in whom the dosage had been raised to 2 tablets a day began to complain of mild drowsiness during the ninth week. Although the drowsiness persisted it did not interfere with therapy, and the dosage was not reduced. There were no other side effects.

BEHAVIORAL EVALUATION OF IMIPRAMINE AND NIALAMIDE IN REGRESSED SCHIZOPHRENIC PATIENTS WITH DEPRESSIVE FEATURES¹

CARL A. LEUTHOLD, Ph.D., F. J. BRADSHAW, JR., M.D.,
G. W. ARNDT, M.D., E. F. HOFFMAN, M.D., AND
VLADIMIR PISHKIN, Ph.D.²

This study was designed to test the effects of imipramine³ and nialamide⁴ in treatment of regressed schizophrenics with depressive features. These agents have generally been evaluated by global clinical impression (1, 2, 3, 4, 5, 6, 7). The present study employed objective measures of behavior change in addition to clinical judgments.

The subjects were 52 regressed schizophrenic patients characterized by at least three of the following features: 1. Psychomotor retardation, 2. Despondency-sadness, 3. Lack of interest, 4. Helplessness-pessimism, 5. Suicidal drive.

Milieu and over-all treatment program were uniform for all subjects. Subjects were divided into 4 treatment groups: imipramine (I), imipramine placebo (IP), nialamide (N), and nialamide placebo (NP). A double blind crossover design was employed. The 4 research medications were administered for 2 6-week periods with a 4-week intervening rest period. After the rest period nialamide and imipramine were exchanged in the drug groups and placebos exchanged in the placebo groups. The dosages for each sequence of 6 weeks were as follows: 1. 50 mg., 2. 100 mg., 3. 150 mg., 4. 200 mg., 5. 300 mg., and 6. 400 mg.

The subjects were evaluated by the MACC Behavioral Adjustment Scale (8, 9) on motility, affect, cooperation, communication and total adjustment. MACC evalua-

tions and independent clinical evaluations by a psychiatrist were made before and after the first 6-week treatment period, at the end of the rest period, and again at the end of the second 6-week treatment period.

The McNemar Test (10) for significance of changes was used to determine clinical and behavioral changes as functions of the 4 treatment conditions.

RESULTS AND DISCUSSION

The first drug phase. During the first 6 weeks each of the active drug groups significantly improved in clinical condition ($p < .005$) as measured by the psychiatrist's ratings. The imipramine group improved significantly in motility ($p < .05$). Improvement in affect was measured for the nialamide group ($p < .05$) and for the placebo groups, IP ($p < .01$) and NP ($p < .025$).

The rest period. When measures taken at the end of the rest period were compared with pretreatment measures the active drug groups no longer showed improvement in clinical condition. In contrast, both placebo groups had significantly improved in clinical condition, IP ($p < .05$) and NP ($p < .025$).

Clinical ratings differentiated the active drug groups from the placebo groups at the end of 6 weeks of treatment and again at the end of the rest period but with a reversal in relative condition of the active drug and placebo groups. The active drug groups lost their earlier gains over the rest period, but the placebo groups were improved at the end of the rest period. It appeared the milieu had a slower but more lasting effect on the placebo patients who operated without the crutch of active medication.

The second drug phase. At the end of the second drug phase clinical evaluations again differentiated the drug groups from the placebo groups. Only the drug groups had significantly improved ($p < .005$). As in the

³ Supplied as Tofranil through the courtesy of Geigy Pharmaceuticals.

⁴ Supplied as Niamid through the courtesy of Pfizer Laboratories.

first drug phase, the imipramine group also made significant gains in motility ($p < .025$). It should be noted that these significant changes were obtained only when measuring the change over the entire 16-week period and not when the pre- and post-measures for the second drug phase were compared.

MACC scale findings differentiated the N and I groups on some factors but did not reveal differences between the combined active drug groups and the combined placebo groups as were found in the global clinical evaluations.

The I group manifested increased motility at the end of each 6-week treatment period, *i.e.*, there was an increase in general motor activity including more frequent and more forceful verbal productions.

Affect scores for the four groups contrasted sharply with the motility scores during the first drug phase. The I group, which alone showed increased motility, was the only group which failed to gain in affect. Higher affect scores are associated with patients who are, in general, easier to get along with, *i.e.*, less irritable, bitter or sullen.

SUMMARY

Imipramine and nialamide were found to be comparable as measured by psychiatrist's clinical ratings of over-all improvement in patients with depressive symptoms. On measures of specific behavioral factors on

the MACC scale the two drug groups were differentiated by improved motility in patients on imipramine and by positive changes in affect in patients receiving nialamide during the first 6 weeks of drug administration.

COMPARISON OF EST AND ANTIDEPRESSANT DRUGS IN AFFECTIVE DISORDERS

JANE E. OLTMAN, M.D., AND SAMUEL FRIEDMAN, M.D.¹

Considerable interest has been displayed recently in the comparative value of EST and drugs in the treatment of depressive states. It has been intimated that antidepressant drugs are inferior to EST with respect to incidence of relapses and length of remissions. However, relevant, well-crystallized statistical data have been lacking. In an effort to answer this problem we have reviewed the records of all female patients with affective disorders who received

EST or antidepressant drugs, admitted to this hospital during the past decade. The following specific data were recorded for each case.

Age at episode of illness. The data were categorized into three significant periods: under 41, 41-60 and 61 or over.

Numerical order of episode. 1st, 2nd, intermediate (3rd to 5th) and late (6th or later).

Diagnosis. The standard nomenclature was followed.

Type of treatment. In the case of EST the

¹ Respectively Ass't. Supt., and Clin. Dir., Fairfield State Hospital, Newtown, Conn.

number of treatments was recorded, specifically whether less than 6; in the case of drugs whether therapy was continued on a maintenance basis.

Multiplicity of attacks. Specifically whether multiple attacks had already appeared or whether the episode represented the only illness thus far.

Incidence of Relapse. Intervals between rehospitalization and/or retreatment on an extramural basis were classified as follows: 1. 0-6 months; 2. 6-12 months; 3. 12-18 months; 4. 18-24 months; and 5. 2 years or longer.

Inasmuch as antidepressant drugs have been used extensively for 2 to 3 years only, intervals beyond that period were not pertinent. Essentially, then, this study is a comparison of how well patients maintain

their status during a 2-year post-treatment phase. The antidepressant drugs used were Tofranil and Marplan.

Approximately 650 individual patients and over 1200 treatment episodes were included in the study. Of the latter, approximately 250 consisted of antidepressant drugs, which have been used practically exclusively here in the treatment of affective disorders in women during the past 2 or more years. It might be indicated that the great majority of patients who received antidepressant drugs have been followed at our outpatient clinic, thereby affording us detailed knowledge of their progress. To avoid unnecessarily detailed statistical presentation in this brief communication, the accumulated data have been summarized as follows.

TABLE 1
Comparison of Length of Remission Following EST and Drug Therapy

Diagnosis	Total No.	EST Duration of Remission				
		< 6 m.	6-12 m.	12-18 m.	18-24 m.	2+ y.
Psychoneurotic reactive depression	151	68	13	11	9	50
Psychotic depressive reaction	93	33	8	3	2	47
Involuntional psychotic reaction	169	56	16	6	4	87
Manic-depressive reaction	571	148	52	36	36	299

Diagnosis	Total No.	ANTIDEPRESSANT DRUG Duration of Remission							
		< 6 m. Com- plete	In- com- plete	6-12 m. In- com- plete	12-18 m. In- com- plete	18-24 m. In- com- plete	2+ y.		
Psychoneurotic reactive depression	80	18		2	16	0	16	2	15
Psychotic depressive reaction	33	7		3	9	0	9	0	3
Involuntional psychotic reaction	22	5		1	6	0	6	0	2
Manic-depressive reaction	105	27		4	24	5	16	4	16

Direct comparison of data in the two groups is somewhat difficult because the majority of intervals in the drug-treated group are still incomplete; consequently, the full duration of remissions cannot be determined as yet. In the EST group, intervals are either complete or the incomplete ones are beyond the 2-year limit. The most precise comparison can be made with respect to relapses within the first 6 months.

In the EST "neurotic" depressive group it is noted that 68 of 151 treatment episodes (45%) were followed within 6 months by relapse that required rehospitalization or retreatment. (This will be designated as "treatment relapse.") This represents the poorest results in the EST group and confirms the generally held opinion that EST is least satisfactory in the treatment of "neurotic" depression. In the drug-treated group, 18 of 80 episodes (23%) were followed by treatment relapse. It should be noted also that in 6 of these 18 instances (33%) the drug had been discontinued within the 6-month period, either through self-discontinuation or other factors.

In the group of psychotic depressive reaction, 33 of 93 EST-treated episodes (35%) were followed by treatment relapse as compared with 7 of 33 (21%) in the drug-treated group. Again, 2 of the 7 (29%) had discontinued the drug. In the involutional group treated by EST, 56 of 169 episodes (33%) ended in treatment relapses, as compared with 5 of 22 (23%) in the drug-treated group. One of the 5 patients (20%) had discontinued the drug. In the manic-depressive group, EST was followed by treatment relapse in 148 of 571 instances (26%) which was identical with the percentage for the drug-treated group, with 27 relapses in 105 episodes. Five of the 27 (19%) had discontinued the drug. The manic-depressive "mixed" sub-group was too small for statistical analysis; however, in general, the results were similar to those observed in the "depressed" sub-group.

It is pertinent to note that superior results with respect to relapses were obtained with both EST and drug therapy in the first attack of manic-depressive illness. Thus in

the EST group only 19% of first attacks were followed by treatment relapse, as compared with 32% for all recurrent attacks. There was no treatment relapse within 6 months in the 10 patients whose first attack was treated with antidepressant drugs.

In over-all comparison within the EST group, it is noted that treatment relapse occurred in 45% of "neurotic" depressions as compared with 28% for all "psychotic" depressions. In the drug-treated group, the corresponding figures were 23% and 24%, respectively. In general, EST in which the number of treatments was less than 6 (or unknown) was followed by a greater incidence of relapse. However, such treatment episodes were relatively few and did not significantly affect the over-all results.

It may be noted that the results with EST observed in this study are similar to those previously recorded,² when appropriate allowance is made for the fact that the earlier study used rehospitalization as the only measure of the relapse phase whereas the current study also included extramural administration of EST as a criterion.

SUMMARY AND CONCLUSIONS

Because of limited temporal factors, it is difficult at present to compare the incidence of "long-term" remissions (2 years or more) in patients treated by EST and those treated with antidepressant drugs. In "psychotic" depressions, treatment relapses, as defined, are certainly not more frequent in drug-treated patients than in the EST group. In "neurotic" depressions, results, with respect to relapses, are definitely more favorable following drug therapy. Premature discontinuation of the drug will lead to a greater incidence of relapses. As a corollary to this, patients treated with drug therapy require more continued follow-up care than those treated by EST. Contrary to our earlier hopes, it is evident that drugs will not affect the recurrent pattern of affective disorders—no more than EST has done. The pattern of repetition of attacks varies greatly from one patient to another.

ACETOPHENAZINE (TINDAL) AND THIOPROPAZATE (DARTAL) IN AMBULATORY PSYCHONEUROTIC PATIENTS¹

HARRY F. DARLING, M.D.²

Piperazine phenothiazines, prior to acetophenazine, were roughly similar in their action (1) and found to work best on introverted or schizoid neurotics or on incipient schizophrenics with primarily neurotic symptoms (2, 3). Reports on the use of phenothiazines generally in neurosis, if one takes a general overview of the literature, would seem to favor the aliphatic phenothiazines and thioridazine but unfortunately these drugs are prone to cause hematopoietic damage, and in the case of the latter a tendency to leukopenia as high as 10% has been reported (4). The writer has used phenothiazines other than piperazines with hesitation in private practice and only when other drugs failed, for the reason that laboratory followup is difficult for both psychiatrist and patient. Both chlorthalidone and chlorprothixine have been used by the writer, the former especially with remarkable results in many cases, but there is still a significant group of psychoneurotics who seem to need phenothiazines, although they often make temporary improvement on other drugs.

Acetophenazine has been used by the writer in psychoneurosis and the purpose of this study is to compare it with one of the older piperazines. Therefore 70 psychoneurotics given acetophenazine have been tabulated and compared with 70 given thiopropazate in previous years. All cases were on medication at least 3 months. Better results were obtained with acetophenazine primarily because there was a relative freedom from disturbing parkinsonism and secondarily because there seemed to be a wider spread of action with the drug and the less introverted patients did better on it. However it did work better on a larger proportion of introverted and preschizophrenic patients than with nonintroverted patients ;

but a significant proportion of the latter type did react to acetophenazine who did not react to other antianxiety agents. There is a larger proportion (two-thirds) of the former type in the study leaving only a sampling of the latter ; frank schizophrenics were excluded.

Drowsiness was the primary disturbing side effect from acetophenazine ; there would have been a smaller percentage had the writer used a smaller initial dose on his earlier patients ; it was usually controllable by reduction of dose. Parkinsonism, which occurred in a few cases, was controlled by reduction of dose or by the addition of an antiparkinsonian agent, or both.

SUMMARY

Acetophenazine is compared with thiopropazate in its action on psychoneurotics. It was a more effective drug primarily because more patients could tolerate it due to a low incidence of parkinsonism. Drowsi-

COMPARISON BETWEEN ACETOPHENAZINE AND THIOPROPAZATE

	Acetophenazine	Thiopropazate
Mean age	34	31
Diagnosis :

CASE REPORTS

SEVERE HYPERTENSION WITH PARNATE

MARIANO F. SONGCO, M.D.¹

Parnate, like the other MAO inhibitors, has been known to cause postural hypotension in some cases. Indeed it is a major side effect to watch out for particularly in patients with a history of hypertension. This is a report of a case where sudden and severe hypertension appeared to have been paradoxically provoked by the administration of moderate doses of Parnate.

The patient is a 67-year-old male who was returned to the Norwich State Hospital for recurrence of depressive symptoms. On admission he was moderately depressed but otherwise asymptomatic. Routine physical examination did not reveal anything remarkable. Blood pressure was 166/92 sitting and 158/84 standing.

He has had three previous admissions within the past 10 years. In each instance, hospitalization was due to excessive drinking resulting in disturbed thinking and behavior accompanied by depressive symptoms. He has also been known to suffer from convulsive seizures ever since he suffered a fracture of the skull 11 years ago. While in the hospital 6 years ago, he had a posterior myocardial infarct from which he recovered uneventfully.

Upon admission, the patient was placed on Dilantin, gr. 1½, Phenobarbital, gr. ½, and Parnate, 10 mg., all given t.i.d. His blood pressure was checked routinely b.i.d. and, in the next 2 days, ranged between 160-170 over 80-90 sitting, and 150-174 over 80-84 standing. On the third hospital day, at about 8:30 p.m., he first complained of severe frontal-occipital headache. About 10 minutes later, he complained of lower chest discomfort and he suddenly developed dyspnea and cyanosis. He was immediately started on oxygen from a portable ward unit. His blood pressure, which was last recorded 3 hours before to be 170/80 sitting, was now 260/90. TPR was 97.2, 120, and 28. He was fully conscious, apprehensive, orthopneic, markedly cyanotic, and had cold,

clammy perspiration. The chest was full of coarse, bubbling rales; heart sounds were muffled, fast, but regular. He was given morphine sulfate, gr. ¼ to allay his apprehension. Meanwhile, in the next 15 minutes, while being transferred to the medical ward, he lapsed into coma. Respiration by this time had become extremely labored and gasping; rate dropped to 14/minute. He was rapidly digitalized intravenously with Digoxin, 0.5 mg. and oxygen was continued through the night. Blood pressure, which was constantly being checked, remained at very high systolic levels for about an hour after which it gradually receded thus: 1 hour from onset, 240/90; 2 hours later, 192/90; 3 hours later, 168/88; 6 hours later, 170/90. The patient regained consciousness about 8 hours after the onset. EKG taken the following morning showed left ventricular hypertrophy and digitalis effects. Eventual recovery was slow but uneventful.

DISCUSSION

In recapitulating what may have happened in this case, two predisposing factors stand out, namely: the initial presence of hypertension and the history of cardiovascular disease, particularly the heart attack suffered 6 years ago. For some unknown reason, Parnate in this case caused a sudden marked rise in the systolic blood pressure instead of the hypotensive effect that is more commonly observed. Most probably, hypertensive encephalopathy leading to coma then ensued and, at the same time, the pulmonary hypertension led to left heart failure and subsequently pulmonary edema.

This case serves to re-emphasize that extreme caution should be exercised when giving Parnate to patients with a history of hypertension, particularly those with cardiac complications. The sudden development of severe headache and any cardio-respiratory symptoms that may follow should be treated as a medical emergency.

¹ Physician-psychiatrist, Norwich State Hospital, Norwich, Conn.

WITHDRAWAL SYMPTOMS FOLLOWING ETHCHLORVYNOL (PLACIDYL) DEPENDENCE

HEBER S. HUDSON, MAJOR, MC, AND HERBERT I. WALKER, CAPT., MC¹

Since its introduction in 1955, ethchlorvynol(1) (Placidyl-Abbott) has attained limited use as a hypnotic and tranquilizer. Published reports of toxicity and withdrawal difficulties are confined to one Canadian article(2) and one Scandinavian report of a reaction following acute overdosage(3).

Case Report: E.S., a 40-year-old right-handed white female began taking ethchlorvynol for increasing anxiety in 1958. On several occasions in early 1960, she had episodes of generalized weakness, mild staggering, nocturnal muscular aches and transient periods of confusion. In December 1960, she began to experience trance-like episodes resembling catatonia with blurred and double vision, increased staggering, headaches, dysarthria, motor incoordination, recent memory disturbance and psychomotor retardation. In early January 1961, she was seen by a neurosurgeon who noticed anisocoria, and advised further work-up but hospitalization was postponed until the patient retired in this area. She was seen here on 17 February 1961, and appeared to be a chronic neurotic. At that time the patient stated that she had been frequently taking Placidyl, 500 mg. at night and occasionally 100 mg. in the daytime. She was advised to stop her medication. Neither the patient nor her husband can recall accurately whether or not she continued the Placidyl in this week prior to admission. On 24 February, her condition had deteriorated somewhat and she complained of confusion, loss of concentration, feelings of unreality and difficult thinking. Hospitalization was advised because of the suspicion of a schizophrenic reaction.

Admission mental examination 3 days later, revealed a thin, slight woman whose speech was circumstantial and tangential. Her affect was, at times, inappropriate and she frequently missed the point of questions. There were no delusions or hallucinations and orientation was preserved. The neurological examination revealed the anisocoria noted above and a medical consultant found no other organic disease. Blood serology, hemogram, urinalysis, electrolytes, urea N., fasting blood sugar and liver function tests were within normal limits. On

28 February, a psychological testing revealed psychoneurosis with hypochondriasis and phobic features, hints of organicity and no evidence of schizophrenia. She became more confused, began to misidentify people, and was observed to have auditory and visual hallucinations. On 1 March, she had 3 grand mal seizures and an EEG revealed bursts of generalized slowing, most prominent in the right frontal area. She was placed on Dilantin, 100 mg. t.i.d. and there were no further seizures. She became more delirious but there was no progression of neurological signs. Skull films were normal and barbiturate and bromide levels were negative. On 3 March, a pneumoencephalogram was read as normal and her spinal fluid revealed clear fluid, normal dynamics, cells and protein. Her course during the next 3 days was stormy with agitation, delirium and vivid tactile and visual hallucinations. Repeated psychological testing revealed severe organic impairment. Massive doses of Thorazine aided her somewhat and suddenly, on 6 March, the hallucinations ceased and only mild confusion remained. An EEG on 8 March showed improvement and a repeat EEG on 16 March was read as normal. She was discharged on 22 March completely cleared and has had no recurrence of the previously mentioned symptoms after 3 months of careful follow up.

Prior to admission, both the patient and her husband denied excessive or increased dosage of Placidyl. As her memory cleared and the confusion lifted, she admitted that she had, on many occasions, taken over 1,500 mg. per day for months on end. The symptoms referred to previously paralleled increased dosage of Placidyl.

A case of Placidyl intoxication and withdrawal is presented which manifested itself with neurological symptoms and a stormy, schizophrenic-like syndrome. This report emphasizes the necessity for adequate supervision of patients utilizing sedative drugs, even those with allegedly negligible side effects.

THE PRESIDENT'S PAGE

THE PSYCHIATRIST'S RESPONSIBILITY FOR MENTAL RETARDATION

Psychiatrists as a group are disinterested in mental retardation. Many have no more accurate knowledge about the retarded than the layman does. Training centers seldom provide serious field study. Residents in psychiatry are unwilling to train in the hospital school. Full time staff positions at residential centers for the retarded go unfilled. There are vacancies, as a consequence, for qualified administrators.

If questioned, most psychiatrists would agree that mental retardation is a subspecialty in their area of responsibility, and then disqualify themselves. Others are filling the vacuum of professed leadership. Is this a serious matter? Should we be concerned that psychiatry as a profession is unable to meet its responsibilities? Or after a long hard look should we admit our mistake, say this is not our field, and bow out? Are there other alternate actions that are appropriate and desirable?

Some of the issues will be faced in the forthcoming conference developed by the Committee on Mental Deficiency under George Tarjan and sponsored by the American Psychiatric Association. It will bring together the American Association for Mental Deficiency and representatives of national bodies in neurology and pediatrics and others.

How important is the psychiatrist in the diagnostic process? Heller's Disease, organic brain disorders, neurologic diseases, childhood schizophrenia and autism may be confused with mental retardation. Medical diagnosis is the physician's job. Perhaps the psychologist can contribute all the skills essential to determination of maturational delay, retardation in learning, distortion of emotion, existence of psychological conflict and emergent disorders from broken and troubled families.

The treatment of aggressive, hostile and destructive behavior that is the product of emotional illness has always been the psychiatrist's responsibility. The same symptoms exist as a cause for treatment or

hospitalization in the retarded. Shall we conclude that if the subject is retarded these symptoms may now be properly delegated for therapy by an educator or other professional?

Is program planning for the detection of mental deficiency, in family and school services, in counseling for courts and probation departments to be the responsibility of the psychiatric agency or some other?

Citizens' organizations interested in the betterment of the treatment of the mentally retarded have effectively utilized the appeal of the defective infant and helpless child. Legislators have listened to their lobby. Schools have been responsive. With growing strength the organizations press for solutions to problems. They are quite unwilling to stand by while psychiatry makes solemn pronouncements about mental retardation being the area of responsibility of psychiatrists but then admit it can provide no doctors to staff facilities or to give leadership.

I happen to believe that emotional disorders and family stress lead most frequently to the need for outpatient treatment or residential services for the mentally retarded. Qualified psychotherapists and competent physicians are essential to proper diagnosis and treatment. In addition effective education, social therapy and vocational training are parts of a rehabilitation program leading to social restoration.

Educational psychologists and teachers with experience in the program of education and training the retarded are emerging as leaders and administrators. Pediatricians have a natural interest because they are often the first to be consulted when a child functions poorly. The neurologist is interested in the aftermath of infectious diseases and in the organic brain disorder. The psychologist is concerned with learning, language, intelligence and vocational rehabilitation and has many points of contact in the field.

If it is agreed the psychiatrist also has an

important contribution to make, then ways must be found to arouse and sustain his interest. Perhaps it would help if all medical students while studying growth and development would receive at least one session on mental retardation. In the neurology clinic an effort might be made to include illustrative cases. The same could be effective in the pediatric clinic. Research in the field under the medical school auspices would help make study of the retarded

prestigious. In my opinion all psychiatric residents should have some training in mental retardation and every child psychiatrist should have a more intensive learning experience.

Premium pay for professionals is a realistic necessity to attract and hold the top flight people the field must have for growth and good performance.

WALTER E. BARTON, M.D.,
President

COMMENTS

THIRD WORLD CONGRESS OF PSYCHIATRY

The congregation of several thousand psychiatrists from 63 countries represents a formidable spectacle with diverse potentialities. The recent World Congress of Psychiatry held at Montreal, June 4-10, seems to have avoided most of the pitfalls inherent in such an undertaking and to have achieved a success that exceeded the most sanguine expectations of its sponsors, or so the unsolicited comments of many participants would seem to show. The work of scientific and administrative staffs combined with the diligent efforts of the lady volunteers yielded a meeting of great professional interest and social satisfaction.

The city provided an enviable environment with its bicultural flavour, and the concentration of the sessions on one floor of the city's largest hotel made for convenience and congeniality. The presence of outstanding international figures lent an undeniable lustre to the week's meetings. The choice of diverse themes for discussion seems to have struck a resonant note in the participants' interest, though the number of sessions running concurrently presented perhaps an excessive choice. Simultaneous translation into the 4 official languages took place in 3 large halls. This meant that all 12 plenary sessions accounting for some 43 papers and 16 panel discussions with 80 speakers were available to listeners despite language limitations. Though costly, this resolution of the barrier to communication should achieve a still greater use at future meetings.

The high quality of the papers presented was probably equalled in value by the opportunities of all to meet distinguished psychiatrists from other lands, to make new friends, and to learn of their problems. This represented a true dissolution of frontiers and humanity's troubles could be seen as knowing no national or geographic boundaries. All continents were represented and though psychiatric conditions vary somewhat with the milieu, they all concern the common denominator, man. The final emergence at the end of the Congress of a new

World Psychiatric Association, which was set up as a consequence of deliberations at this Congress, was a fitting climax to a meeting which aimed at the integration of efforts of psychiatrists of the nations represented.

The Congress, sponsored by the Canadian Psychiatric Association, Dr. Jean Saucier, President, and McGill University, Dr. D. E. Cameron, Chairman of the Organizing Committee, enjoyed the patronage of His Excellency Major-General Georges P. Vanier, D.S.O., M.C., C.D., Governor-General of Canada. Opening ceremonies took place Monday morning, June 5, following which the scientific sessions were inaugurated by Dr. Jean Piaget of Geneva who spoke, in his academic lecture, on child development. It seems fitting that this great psychologist, who has made such fundamental contributions to our understanding of the beginnings of mental life, should initiate the meeting whose considerations spanned all ages. Monday afternoon was devoted to 3 major plenary papers enunciating three leading themes to be considered again and again in the succeeding days from various points of view. First, Dr. H. C. Rümke of Holland discussed phenomenology in the sense of descriptive psychiatry and from his broad experience drew an outline which set the background of psychiatry's solid basis. This was followed by the kaleidoscopic enumeration of experimental approaches in former and current use by Dr. Jules Masserman of Chicago. Finally, theories in psychiatry were reviewed in scholarly fashion by Dr. Henri Ey of Paris.

Other major events of the Congress took place on Wednesday, June 7. In the early afternoon the academic lecture on internal inhibition was delivered by Dr. H. W. Magoun. This represented an account of brilliant explorations of the central nervous system by the highly skilled techniques of neurophysiology on which a firmer psychiatry may yet be built. Following this there were convocation ceremonies at McGill

University where honorary degrees were conferred on Dr. W. S. MacLay of England, Dr. Henri Ey of France, and Dr. C. B. Farrar of Canada. A similar ceremony was held shortly after this at the University of Montreal with Dr. Jean Delay of France, Dr. Ugo Cerletti of Italy, and Dr. C. Lagache of France being the recipients. The same evening saw 3,000 people assembled in the McGill University gymnasium to hear scientific creativity discussed by three Nobel laureates who were introduced by Dean D. L. Thompson with his particular mixture of incomparable wit and scholarship. As a first speaker, Dr. A. Szent-Gyorgyi quickly made his way into the hearts of the audience by getting down to the task of dealing with the rather torrid temperature by removing his coat and rolling up his sleeves. His vigour, enthusiasm, and honesty were transparent to all who followed his description of scientific work, and in particular his own, with absorbed interest. He emphasized that a scientist, like a creative artist, finds satisfaction in building something new. He pointed out that in scientific creativity, posing the problem was already half the work. Lord Adrian, by contrast, was a restrained, aesthetic figure who stressed the value of newly-developed techniques and instruments as contributing heavily to the advancement of science. He pointed out that research is based on what appear to be reasonable theories and he contrasted the difficulties in biological research to those in the physical sciences since in the former there was always interaction with the environment. This was particularly true in medical research. He warned against forcing young scientists into too rigid a mould and inculcating excessive respect for their scientific elders. The third speaker, Dr. Linus Pauling, apparently had a carefully prepared script which he shortly abandoned to make excursions into chemistry which demonstrated his vivid qualities as a teacher. He referred to his own exciting studies of the haemoglobin molecule in sickle-cell anaemia. He emphasized the working of the unconscious mind in the utilization of clues. He felt that each scientist working creatively did so in his own unique way. He also emphasized that excessive involvement in non-scientific activities such as his own ef-

forts related to world peace constituted a distraction interfering with research activity. These 3 different distinguished personalities managed to imbue the audience with some of their own feelings for scientific creativity so that all those who attended left invigorated and inspired.

Another event of academic significance took place at the banquet Thursday night with the awarding of honorary membership in the Canadian Psychiatric Association to three internationally recognized psychiatrists, namely Dr. William Sargant (England), Dr. Lopez-Ibor (Spain) and Dr. Robert Felix (U. S. A.).

After the opening day, and excepting Wednesday and Saturday, plenary sessions were held both morning and afternoon with 4 to 6 eminent speakers each. The titles of these sessions and the participants were:

Mental Hospitals: MacLay (England), Fossum (Norway), Napolitani (Switzerland), Kubie (U. S. A.);

Neurophysiology: Selye (Canada), Himwich (U. S. A.), Sawyer (U. S. A.), Reiss (U. S. A.), Penfield (Canada);

Child and Family Psychiatry: Leonhard (Germany), Scott (Canada), Seguin (Peru), Cameron (England);

Psychotherapy: Megrabian (U.S.S.R.), Hoff (Austria), Schultz/Luthe (Germany/Canada), Cameron (Canada), van der Waals (U. S. A.);

Physical Therapies: Kalinowsky (U. S. A.), Hirose (Japan), Freeman (U. S. A.), Caffey (U. S. A.), Jus (Poland);

Social Psychiatry: Macmillan (England), Funkenstein (U. S. A.), Redlich (U. S. A.), Bustamante (Cuba), Boss (Switzerland);

Concepts and Methods: Weinroth/Linn (U. S. A.), Stengel (England), Kallmann (U. S. A.), Mirsky (U. S. A.), Lagache (France);

Psychopathology: McGrath (Ireland), Grinker (U. S. A.), Lopez-Ibor (Spain), Lidz (U. S. A.), Snezhnevsky (U.S.S.R.).

A definitive account of the rest of the programme which filled the remaining 5 days could not be achieved by anything less than a monograph. An indication of the variety of topics and number of sessions might convey better than any other way the nature of the programme to which Con-

gress members were exposed, or subjected. There were 49 panel discussions, 16 of which were given in halls with simultaneous translation. Seven subsections were devoted to psychopharmacology in order to accommodate the great interest in this field. Three extra subsections for forensic psychiatric and autogenic training and one for experimental psychopathology were also necessary.

Panel discussions were as follows: Addiction; Alcoholism; Association for the Advancement of Psychotherapy; Atypical Endogenous Psychoses; Autogenic Training; Child Psychiatry; Community Mental Health; Corticovisceral Mechanisms; EEG Changes in Human Psychopharmacology; Eliminating Mental Hospitals; Existential Psychiatry; Experimental Psychopathology; Family Psychiatry; Forensic Psychiatry; Geriatrics; Group Psychotherapy; Juvenile Delinquency; Medical Psychology; Mental Retardation; Perceptual Isolation; Planning National Psychiatric Programmes; Pseudoneurotic Schizophrenia; Psychiatric Nursing; Psychiatric Occupational Therapy; Psychoanalysis; Psychoendocrinology; Psychopathological Art; Psychopharmacology; Psychosomatics; Psychotherapy of Psychoses; Religion and Psychiatry; Sleep and Dreams; Social Therapy and After Care; Spanish-speaking Psychiatry; Therapeutic Community; Training in Psychiatry; and Transcultural Studies.

It would be invidious to make a distinction between these panels on the basis of their quality, but from the standpoint of popular interest, it was apparent that those concerning the developing individual, the family, and the community attracted overflow audiences. As might be anticipated, the panel on psychopharmacology chaired by Dr. Jean Delay was extremely popular. The approach was novel and effective in that 6 subsections convened in the afternoon to discuss the individual contributions of the morning. As if this were not enough, it was necessary to set up 3 other sessions in the general programme to take care of still more papers representing only a fraction of those submitted on the topic of psychopharmacology. The subject of perceptual isolation, while exciting much interest and

being impressively presented, was said by one participant to have pretty well run its course for the time being, and would have to wait the passage of considerable time before it took a new lease on life. The panel under Dr. Robert Felix on planning national psychiatric programmes had an extremely important topical appeal and stimulated thinking in this area where many newly-developed countries have problems which, by many Western standards, are unsophisticated but difficult. By the same token, the panel on transcultural studies struck a responsive note as evidenced by the attendance and interest, a testimony to its chairman, Dr. Alexander Leighton and his associates. The panel under Dr. P. J. van der Leeuw of Holland on the place of psychoanalysis in training, teaching, and research described the various aspects of this important approach with much cogency. Kubie dealt with the testing of some of the assumptions of psychoanalysis with incisive clarity. Consideration of the contributions of psychology to psychiatry proved to be a most popular and stimulating panel under the leadership of Dr. Joseph Zubin. This covered a wide range of work from the development of conditioned emotional responses through brain mechanisms in behavior to ulcer formation, depression in post-traumatic amnesia and Piaget's consideration of the application of his findings on conceptual development to psychopathological situations. Finally, the session on sleep and dreams under the eminent leadership of Dr. Nathaniel Kleitman was particularly fascinating and indicated that a great deal may be expected to develop further in this rejuvenated field.

The general programme concerned 36 general headings and was divided into 64 sessions at which a total of 315 papers were given. Some of the most important communications given at the Congress were read in one or other of these sessions listed herewith.

General Programme: Aftercare; Alcohol & Drug Dependency; Biochemistry; Children; Communication; Community Mental Health; Concepts & Methods; Depression; EEG; Family Psychiatry; Forensic; General Hospitals; Genetics; Geriatrics; Group Psychotherapy; Hypnosis; Juvenile Delin-

quency; Neuropsychiatry; Organic Psychoses; Personality Development; Physical Therapies; Psychiatric Hospitals; Psychoanalysis; Psychoendocrinology; Psychopathology; Psychopharmacology; Psychophysiology; Psychosomatics; Psychotherapy; Schizophrenia; Social Psychiatry; Social Stress; Students; Suicide and Death; Teaching; and Transcultural.

The great variety of topics dealt with pointed up the many basic differences in approach. This was most evident in the Tuesday morning session on concepts and methods in which Weisman and Figlioli delivered papers on aspects of existential psychiatry to which Nelson contributed a vigorous critique. Bassin of the U.S.S.R. spoke of the incompatibility of Pavlovian psychiatry with psychoanalysis and was followed immediately by Bridger of the U. S. A. who emphasized the similarities between the two systems. One commentator has suggested that this would be a very fruitful area for future collaboration with the Russians if it were approached from the point of view of our attempts to make Pavlovian theory more meaningful for us rather than from the point of view of trying to sell Freudian theory to the Russians under the guise of there being no difference. Other papers such as this utilizing a psychoanalytic frame of reference were read in various sections according to their appropriateness to the theme, with one session devoted to papers of more specialized interest to analysts.

The place of the general hospitals in psychiatric care received vigorous discussion and an enthusiastic reception. Consideration of the place of teaching indicated that much thought and reappraisal is going on in this area. An important contribution by Margolin raised several critical issues regarding the inadequacy of present training for the job to be done and the possibility of turning out future graduates in medicine more specifically trained for the roles they have to fill. Concern for the student was further emphasized by 6 reports on studies of medical students which was summarized in superb fashion by the chairman, Dr. Martin Roth. Papers by Russian psychiatrists emphasized social and biological factors in determining and curing clinical syndromes.

Organization of community services, and concern with the psychoses, particularly schizophrenia, seemed to be their main areas of interest.

Many of the papers at the Congress concerned a topic of cardinal importance to psychiatry—namely, communication, though they were not necessarily subsumed under that heading. An important study on conditioned avoidance in monkeys was reported by Dr. I. A. Mirsky in which a closed television circuit was used to isolate the animals from each other so that only the facial expression of the one perceiving the conditioned stimulus could communicate concern to the other with the response bar. Designed with scientific rigour, this study breaks new ground in both the recognition and understanding of the communication of affect which people engage in daily, at conscious and unconscious levels. An experimental investigation of the importance of the heartbeat rhythm of the mother to the infant was reported by Dr. Lee Salk. He showed in his perceptively conceived and elegantly executed work that the exposure of newborn infants to a normal heartbeat sound at 72 paired beats per minute resulted in faster weight-gain and decreased crying. The tranquilizing effect of the normal heartbeat rhythm was also demonstrable in older children hastening the onset of sleep.

Various phases of biological development received critical attention. The importance of newer concepts in genetics was expounded by Dr. Franz Kallmann at a plenary session and interesting papers on disorders in identical twins by Drs. Kolb and Pilot were given. An original contribution was also made by Dr. M. Straker who described the psychiatric evaluation of 38 Caesarian-born adults who showed differences in reaction to stress in that they had many fewer somatic symptoms than two other groups with whom they were compared. He pointed to a re-emphasis on birth as a meaningful experience. Erudite biochemical studies were reported at 3 general programme sessions and deserve much fuller description and consideration than is possible here. A series of studies of great fundamental importance in the area of endocrinology were described by Dr. W. C. Young whose observations of the alteration

of sexual development and subsequent behavior in the female offspring of young rodents exposed to intra-uterine androgens have far-reaching implications. These presumably tie in with the type of refined study of electrical activity in the rhinencephalon in relation to hormonal activation being made by Dr. C. H. Sawyer and his group as reported at one of the plenary sessions. It would seem that neurological and endocrinological studies are meeting in this area which Dr. J. Frank named as the possible seat of empathic capacities.

A final activity of considerable interest was the film programme which went on practically continuously throughout the week. Some 26 films on various aspects of clinical and experimental psychiatry were shown, most of them more than once. They attracted greater interest than anticipated

by the number of seats provided.

CONCLUSION

In closing this attempt to review the Third World Congress of Psychiatry, it should be remarked that it has not been possible to achieve the impossible. No one could encompass this meeting in its entirety. Too much took place, too many papers ran concurrently for anyone to experience it all. Like the fable of the elephant and the blind men, it was felt in different ways. Only by implication could one infer that what one touched was part of a considerable colossus which, like the elephant, was packed with wisdom and like that beast would go trumpeting on over incredible obstacles but responsive to the will of its trainer.

Robert A. Cleghorn, M.D.

ACCOMMODATION

All our lives long we are engaged in the process of accommodating ourselves to our surroundings ; living is nothing else than this process of accommodation. When we fail a little we are stupid. When we flagrantly fail we are mad. A life will be successful or not, according as the power of accommodation is equal to or unequal to the strain of fusing and adjusting internal and external chances.

—SAMUEL BUTLER
(The Way of All Flesh)

IDEA AND REALITY

I know not anything more pleasant or more instructive, than to compare experience with expectation, or to register from time to time the difference between idea and reality. It is by this kind of observation that we grow daily less liable to disappointment.

—DR. JOHNSON

CORRESPONDENCE

ACTION FOR MENTAL HEALTH

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY:

SIR: The final report from the Joint Commission on Mental Illness and Health as the publication *Action for Mental Health* is a monumental, encyclopedic document prepared under the auspices of a dedicated, vitally concerned group of people—"a blue-ribbon team of experts."¹ As a source of authority and reference it may stand the test of time but much is already outdated or may never be accepted as sound advice. Its acceptance by 42 of the 45 members of the Commission is not conclusive of infallibility.

One recommendation is for everybody to get into the act by doing something about mental health; to develop counselors out of lay persons who might be interested after short courses of informal training or instruction. Sound professional and lay judgment should dictate caution in the acceptance of persons to serve in such capacity. Far too many pseudo-experts are basically abortive physicians who are more than willing to tamper with the health of other people and play God in the manipulation of their minds and emotions. In the absence of a definition of what constitutes positive mental health, the hazards from the use of such participants are considerable.

To receive the endorsement of the psychiatric profession, the report should guarantee the basic tenets of medical service: tend the sick but do nothing to harm them, and to cure if possible. The Commission recognizes the complexity of the problem by reference to "biological, psychological and sociological forces" acting on behavior complementing "a given potential for mental health or illness."² Comparison with the eradication of certain communicable and nutritional diseases is thus misleading. No possibility currently exists for mankind to

stay the tide of material "progress" (?) and come abreast of good societal mental health. Shortage of qualified personnel is not a justification for lay persons to join the "therapeutic team." Already too many leaders in various walks of life such as "chiropractic psychiatrists," "hypnotherapists," and "counselors" with little or no preparation plus the hypomanic or sociopathic individuals push to the fore as community "do-gooders." Several years ago California discovered "convenors": persons who attended a 2-day conference on mental health. Counselors and convenors are potential public menaces unless closely restrained by competent supervision. Even social organizations have acted misguidedly in a manner ill advised for want of ethical restraints, publicizing presumed knowledge in a manner familiar in merchandising products. The use of clichés and convenient statistics as alleged facts found in publications of apparent authenticity should be discouraged. Counselors are apt to venture where physicians fear to tread.

Another recommendation of the report is to convert large mental hospitals into rehabilitation centers for chronic diseases, including mental illness. Against this, Miss Loula Dunn, a member of the Commission, makes a cogent argument and quite rightly states, "nothing can be gained by perpetuating the concept of the independent chronic disease hospital." Mike Gorman,³ probably less familiar with the nature of the problem, supports the proposal. In view of the convincing showing that mentally ill patients have a repellant effect on the public, there is no reason to expect greater acceptance in the midst of physical semi-invalids and invalids. Social convictions do not alter materially with the loss of an appendage or the acquisition of a chronic physical ailment. The result may be the establishment of a new substandard class of human beings in a setting that does not promise better

¹ David J. Vail, Mental Health Newsletter, State of Minnesota, May 1961.

² Un-numbered quotations taken from *Action for Mental Health*.

³ Speech of April 27, 1961, Sacramento, Calif.

services than the old mental hospitals. The direction of such institutions by lay administrators reopens the issue on the merits of lay administrators *vs.* medical directors in providing medical facilities for a captive clientele.

Despite the promise of "rashness" in bringing a new day to the treatment of the mentally ill, the recommendation for 1000-bed mental hospitals is ultraconservative. It denies meaning to a recognized need for medical superintendents in the operation of public mental hospitals. The 1000-bed hospital, with an expected annual admission rate of approximately 500, is beyond the capacity of any physician to know and serve the needs of the individual patients. When Dr. Harry Solomon in 1958 spoke of the obsolescence and antitherapeutic characteristics of mammoth state hospitals, he suggested that these institutions be dismembered into smaller, independent, complete psychiatric units. The proposal was received with mixed feelings by commissioners and superintendents responsible for the operation and continuance of such institutions. Apparently, they could not envision the possibilities of such reorganizations with certain areas of common use like acute surgical and medical needs, food service, general maintenance, *etc.*, remaining more or less unchanged to serve the entire compound. His aim was to end construction of hospitals of excessive capacity.

Since this memorable declaration, GAP (Report No. 46) quoted with approval the recommendation of Dr. Thomas Kirkbride, who wrote about 80 years ago that mental hospitals should be limited to 250 beds "with 500 as the undesirable top limit." The Surgeon General's Report, *Planning for Mental Health Facilities* issued December, 1960 recommends 600 beds as the maximum capacity. Along comes Dr. Francis J. O'Neill,⁴ during the 1961 annual meeting of the APA, to belabor the issue by arguing the merits of large institutions *vs.* smaller ones; he doubts "patients receive any better treatment or have any better chance of recovery in a small hospital because of its size alone"; then he goes on to say "that there are advantages in the small hospital."

This is quite a concession! He also injects the economic factor which has been pretty well exploded.

From personal experience with a hospital that expanded in the past 16 years from an average census of 336 to about 580, I know it need not be more expensive to operate a small hospital above a minimum of 250 to 300 beds. Operating costs *per diem per capita* for the Nevada State Hospital during the past decade have been only slightly in excess of the national average. Expansion has reduced the superintendent's participation in clinical and personalized services to patients and concerned relatives.

Too much lip-service has been given to clichés like "milieu therapy," "homelike atmosphere," "personalized attention," *etc.*, to now approve 1000-bed hospitals. Such offerings are simply not realistic for large institutions where administration depends upon mass decision rather than consideration of individual patients. The recommendation is a disappointment to those who recognize the merits inherent in well directed small hospitals. Furthermore, in many areas of the country, large institutions would preclude their location in proximity to the communities served. The report may justify the continuing expansion of the hospital in Nevada, clearly against the interests of half of the state's population living at a distance of 450 miles from it.

The proposals for state programming are vague and misleading. Clinics for the mentally ill are referred to as "the fulcrum of effort to remove the barriers isolating mental hospitals from the community." In one instance they are not only to render clinical services but take leadership in providing community mental health education. Elsewhere advice is given to have mental health education "left for the health departments and mental health associations." In another instance the report invites hospitals to make closer contact with communities by actively participating in local programs. There appears to be a confused overlapping in assignment of the various phases of a total program. A clearly delineated plan of organization for state programs is still needed.

On the subject of research the implications are that it be encouraged and supported in every nook and cranny "out of a

⁴ Mental Hygiene News, NYS Dept. Mental Hygiene, May 1961.

wish to do something." This is not sufficient justification for a generous use of public funds. Support of research centers requires little argument but the report's proposals seem to ask for search parties "to find a needle in a haystack." Americans may be "alarm-minded" and "action-oriented" but this is poor reason for loose spending of public funds, especially while "scientists face (the) task with an incredibly small fund of knowledge," and mental health programs depend upon "an article of *scientific faith* rather than an applicable *scientific truth*."

The attitude towards physical therapies seems deprecatory. No direct acknowledgment is given the role played by pharmacology and shock treatment in reversing the tide in the number of hospitalized patients. One of the anomalies of our professional thinking has been to overstress the influence of psychotherapy that is given before, during, and after the physical therapies. This does not deny the merits of psychotherapy as of adjunctive value. Persons emerging

from mental illness are not necessarily naked babes in the woods requiring the wisdom and guiding hand of a so-called mental health specialist for reorientation to community living. The learning experience of hospitalization should include some preparation for the ordeal. No convincing evidence yet exists that "half-way houses" (often third rate boarding houses) and "clubs" for expatients are necessarily helpful on the road back into society.

The implied and expressed medical viewpoints in the report seem biased in favor of popular rather than practical judgments. The Commission recognized its opportunity for "a chance of a lifetime" but lost it by not distinguishing between "faith" and "truth." A more fruitful document might have resulted from fewer debatable recommendations, fewer personal preferences, and more carefully considered objectives.

Reno, Nev.

PSYCHOANALYTIC METHODOLOGY: A REPLY TO DR. LEHRMAN

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY:

SIR: I doubt that the readers of this Journal need to have their attention directed to the fact that the "fundamental error" referred to by Dr. Nathaniel S. Lehrman in his correspondence on page 1045, May 1961, resides *not* in psychoanalytic methodology, but in his misunderstanding of the methodology and its theoretical foundation. Nevertheless, it would be remiss if these pages did not contain a correction of these misconceptions, even if it is only for the record.

Dr. Lehrman writes "Say what comes to mind" is the admonition to the patient. The initial response which then spontaneously occurs is a fundamental part of the 'material' upon which the treatment is based. In practice, this initial response tends to be taken as the truest and most accurate expression of the patient's most profound feelings, of his 'Unconscious.' Lest there be

any doubt about Dr. Lehrman's intentions, he later reiterates this by stating that "psychoanalysis . . . seems at times to accept this response as valid, accurate and undistorted."

The reason I feel my reply is primarily for the record, is that amongst the basic cornerstones of psychoanalytic theory is the widely known premise that dreams have a *latent* as well as a manifest content. Similarly, who amongst us is not aware that underlying the "initial response" to a parapraxis in the form of claiming forgetfulness, are probably unconscious wishes. Certainly such fundamental psychoanalytic concepts do not sound like "the incorrect acceptance of the initial response as essentially valid."

Psychoanalytic technique recommends that we listen to our patients with an evenly hovering attention. In contrast to intent concentration, this enables us to observe more than the verbalized "initial response." The implications, allusions, gaps, thematic

sequences, tone of voice, posture, and a host of other nonverbal communications along with the analyst's own associations deserve our attention if we hope to begin to apprehend the unconscious.

While reading the first part of Dr. Lehrman's letter I wondered if he was not confusing Breuer and Freud's original cathartic method or Jung's diagnostic word association test with psychoanalytic methodology. This hope was shattered when I read of his wondering if this alleged error is not partly responsible for both the unfortunate disruption in the families of some analysands and the discouraging pessimism so pervasive today about the possibility of harmonious human relations. He does not explicitly rule out the possibility of other explanations for these phenomena. It might be well at this time to note one of many other possible explanations for each.

The aim of psychoanalytic therapy is alteration in the structure of the patient's personality so that he might achieve what

his endowment would have permitted had he not been thwarted by his emotional illness. It is not difficult to conceive of success in such a therapeutic venture resulting in disruption of family stability provided that stability was dependent in part on the patient's neurosis. The limited scope of this communication prevents further discussion of this vital point.

Is it not possible that the pessimism regarding interpersonal relations that Dr. Lehrman refers to is a result of an historical comparison of society's startling technological advances with the relative lack of progress in human relations over the past thousands of years? Admittedly psychoanalytic methodology resembles the methodology of the historian, but elaboration of this also would be beyond the scope of a reply to Dr. Lehrman.

Saul I. Harrison, M.D.,

University of Michigan Medical Center,
Ann Arbor, Mich.

REPLY TO THE FOREGOING

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR : The syntheses required for scientific progress can be achieved only by the "controversial" confrontation of differing ideas. Although Dr. Harrison's specific criticisms seem to bear only tangential relevance to the point of my letter, he does however, raise certain issues warranting further examination.

My letter sought to point out that the tendency in psychoanalysis to accept the initial feeling response to or about other people as quantitatively accurate was erroneous because it failed to reckon with the exaggeration of the painful and the hostile inherent in any initial response. The overestimation of interpersonal hostility resulting from this error seems at least partly to underlie the psychoanalytic belief that man and society, son and father, can never get along amicably without basic sacrifice on the part of one or the other. This rather cheerless attitude toward social and intra-familial differences seems to foster the social hopelessness and family disruption also mentioned in my letter.

While Dr. Harrison is correct in pointing out that psychoanalysts do not *always* take the initial response as quantitatively valid, my letter merely indicated that they do so with sufficient frequency to have evoked the pessimistic social attitudes that have been mentioned, and to view these attitudes as thereby proven.

His sixth paragraph criticism seems to overlook the principle of multiple determination so important both in psychoanalysis and in thinking in general. The fact that social causes contribute to contemporary hopelessness in no way denies that psychoanalytic methodology may do so too. Denying the role of psychoanalysis in helping to shape contemporary American social attitudes seems neither accurate nor responsible, particularly when we note the widespread acceptance of the dehumanized, unconsciously cynical psychoanalytic view that noble human motivations are "really" sexual or aggressive in basic origin; this philosophy tends to denigrate ideals and to see a Moses and a Jesus, a Luther and a Lincoln, a Shakespeare and an Einstein as "basically" sublimated beasts.

His seventh paragraph seems almost inadvertently to confirm my letter by demonstrating how psychoanalysis can sometimes affect families in a disruptive way. It implies rather clearly that the analyst sees his sole responsibility, rather than his prime one, as toward his patient alone. In so seeing his task, the analyst tends to subordinate or exclude the patient's spouse in his consideration of the problem, thus setting the therapeutic relationship up in such a way that it becomes significantly easier to scapegoat the absent marital partner. On the basis of information about the marital relationship obtained primarily or exclusively through one pair of biased eyes, the analyst then decides, as Dr. Harrison points out, when a marriage is too neurotically-based to warrant continuation. I am sure that Dr. Harrison has had the same experience as I in discovering how unreliable *any* interpersonal conclusions based on one biased firsthand observer can sometimes be; Freud himself discovered this fact when he found his patients' infantile memories were false.

Dr. Harrison's last paragraph suggests still another important psychoanalytic error: the mistaken tendency some analysts still have to see themselves as merely observers of patients rather than as active participants in a treatment process. But such a denial of participation does not seem completely consonant with the historic responsibility of the physician. The presence of such attitudes within the medical profession alone is unfortunate enough. When, however, they become important in mass communication industries—along highly an-

alyzed Madison Avenue, for example, the clarity of thinking and sense of personal responsibility our country and our world need so desperately today are hardly strengthened.

The exaggeration of interpersonal hostility implicit in psychoanalytic methodology¹ would then seem to have led to several unfortunate consequences, some of which Dr. Harrison's letter seems to suggest or even confirm. One of the most important appears to be its denial that the relationship between subordinate and authority—son and father, man and society—can ever be truly mutual. This anarchistic, hopeless attitude toward the very existence of social structure stands in sharp contrast with the optimistic biblical attitude that authority can be loved and respected, with the responsible democratic belief that social authority can be made better, and with the courageous scientific concept that human search can solve human problems. Since a major reason for the popular acceptance of the anarchism in this philosophy has been the medical and scientific prestige it carries, it would seem to behoove us, as doctors and as scientists, to begin to understand it and correct it, starting within our own field. Even if our only motivation were our recognition of the therapeutic danger of hopelessness, this would still seem to be our responsibility as physicians, because of the vital role hope plays in healing.

Nathaniel S. Lehrman, M.D.,
Great Neck, N. Y.

¹ This point is discussed in some detail in: *Diseases of the Nervous System*, 22 : 201, April 1961.

The end of society is peace and mutual protection, so that the individual may reach the fullest and highest life attainable by man. The rules of conduct by which this end is to be attained are discoverable—like the other so-called laws of nature—by observation and experiment, and only in that way.

—THOMAS HUXLEY

NEWS AND NOTES

FIRST PERUVIAN CONGRESS ON NEUROPSYCHIATRY.—The published proceedings (508 pages) bears date March, 1960 and has just been received (July, 1961).

The Congress was organized by the Neuropsychiatric and Medico-Legal Society of Peru in commemoration of the 20th anniversary of the foundation of the Society.

The Congress was held in Nov. 1958 at Lima. The fields, both of psychiatry and neurology, were widely covered and besides the Peruvian contributors there were participants from Argentina, Chile, Bolivia, Uruguay, Ecuador and Brazil.

One especially interesting contribution by Dr. J. O. Trelles reviewed the neurological teaching of Jean-Martin Charcot, John Hughlings Jackson, Constantin von Monakow and Kurt Goldstein. The report includes portraits of these 4 masters.

PERCIVAL BAILEY LECTURE.—Dr. Benjamin Pasamanick, Professor of Psychiatry at the Ohio State University and Director of Research at the Columbus Psychiatric Institute and Hospital has been named the Percival Bailey Lecturer for 1961. He will speak on "Some Misconceptions Concerning Racial Differences in the Prevalence of Mental Disease" at the Illinois State Psychiatric Institute in November of 1961.

THE SOCIETY FOR THE SCIENTIFIC STUDY OF SEX.—The fourth annual meeting of the Society will be held at 9:30 a.m., Nov. 4, 1961, in the Barbizon Plaza Hotel, 106 Central Park South, New York City.

The topic for the morning session: "Sex and Aging." Discussants: Dr. Harry Benjamin, Dr. Lissy F. Jarvik, Dr. Joseph T. Freeman, Mrs. Donald Armstrong. Chairman: Dr. Hugo G. Beigel.

The topic for the afternoon session: "Sex factors in Schizophrenia." Discussants: Dr. Bernard C. Glueck, Jr., Dr. Jules D. Holzborg, Dr. Lothar B. Kalinowsky, Dr. Sandor Rado. Chairman: Dr. Franz J. Kallman.

AMERICAN PSYCHOSOMATIC SOCIETY.—The 19th annual meeting of the Society will be held at the Sheraton Hotel in Rochester, New York, on Friday, Saturday, and Sunday, Mar. 30, 31 and Apr. 1, 1962.

The Program Committee will welcome abstracts of original work to be presented at the meeting either by members or non-members of the society. Abstracts should be not more than 2 typewritten pages, and should be submitted in 11 copies. Deadline for submission is Dec. 1, 1961.

Abstracts should be addressed to Stewart Wolf, M.D., Chairman, Program Committee, 265 Nassau Rd., Roosevelt, N. Y.

TRAINING IN CHILD PSYCHIATRY.—The Department of Psychiatry at the University of Washington School of Medicine in Seattle, Washington, announces the establishment of a two-year residency in child psychiatry. The comprehensive training program includes not only experience on inpatient and outpatient child psychiatry units, but also supervised liaison with schools for normal and emotionally disturbed children, a resident home for unwed mothers, a resident home for delinquent boys, and other community services and agencies. There are opportunities for research and teaching. The stipends are ample. The program is under the direction of Dr. Raymond Sobel, Associate Professor, Psychiatry.

NORTH PACIFIC SOCIETY OF NEUROLOGY AND PSYCHIATRY.—The annual meeting of the Society was held in Harrison Hot Springs, B. C., on April 7 and 8, 1961. The following officers will serve for the year 1961-1962: President: Robert S. Dow, M.D., Portland, Oregon; President-elect: Robert M. Rankin, M.D., Seattle, Washington; Secretary-Treasurer: Thomas H. Holmes, M.D., Seattle, Washington; Past-President: Peter O. Lehmann, M.D., Vancouver, British Columbia; Executive Committee: Edward K. Kloos, M.D., Portland, Wallace Lindahl, M.D., Seattle, and R. L. Whitman, M. D., Vancouver.

BROOKLYN PSYCHIATRIC SOCIETY.—Meetings are scheduled for the following dates : Oct. 19, 1961—"Presidential Remarks" by Edward F. Falsey, M.D., and "Recent Progress in Psychiatric Research" by William Malamud, M.D. ; Nov. 16, 1961—"The Office Treatment of Schizophrenia," Gustav Bychowski, M.D., Moderator ; Feb. 15, 1962—"Rehabilitation Facilities for the Emotionally Ill" by Joseph Palevsky ; and Mar. 15, 1962—"Basic Concepts in Psychosomatic Medicine, with Special Regard to Therapy," Ralph Moses Kaufman, M.D., Moderator. Scientific sessions are held at 8:30 p.m. in the auditorium of Brooklyn State Hospital, 681 Clarkson Ave., Brooklyn 3, N. Y. and are open to the profession.

FIRST INTER-AMERICAN CONFERENCE ON CONGENITAL DEFECTS.—This Conference will be held at the Statler Hotel, Los Angeles, Calif., Jan. 22-24, 1962, under the sponsorship of the National Foundation and the University of Southern California. General Chairman : Dr. Norman H. Topping, President, University of Southern California.

Program Topics : 1. Genetic Defects : Hemoglobin, Galactosemia, Gargoylism, Amino acid defects. 2. Structural Defects : Chromosome abnormalities, Mongolism, Central nervous system defects, Genito-urinary defects, Eye defects. 3. Clinical Manifestations of Genetic and Structural Defects.

Sessions to be held at Los Angeles County Hospital and to include patient demonstration of Sick cell anemia, Cooley's anemia, Monocytic leukemia, Galactosemia, Phenylketonuria, Gargoylism, Porphyrinuria, Cystinuria, Franconi's syndrome Cystic fibrosis, Genito-urinary defects, Eye anomalies, Chromosomal aberrations, Mongolism, Hydrocephalus, Spina bifida.

For further information : Stanley E. Henwood, Executive Secretary, International Medical Congress, Ltd., 120 Broadway—Rm. 3013, New York 5, N. Y., COrtlandt 7-2400.

NORTH SHORE HOSPITAL SEMINARS 1961-62.—The opening lecture in the Seminars of 1961-62 on "Mental Hygiene" will be

held at the hospital at Winnetka, Ill., on Oct. 11, 1961 at 8:00 p.m.

Mr. David McK. Rioch, Walter Reed Army Institute of Research, Washington, D. C., will speak on "The Challenge of Survival in the Atomic Age."

AMERICAN OCCUPATIONAL THERAPY ASSOCIATION.—The annual conference of the Association will be held at the Sheraton-Cadillac Hotel, Detroit, Mich., Nov. 6-8, 1961.

NATIONAL ASSOCIATION FOR MENTAL HEALTH.—This Association together with the National Institute of Mental Health have recently published the twelfth edition of the Directory of Outpatient Psychiatric Clinics, compiled by the Biometrics Branch of the Institute. It contains the latest available statistics, as of April, 1959, giving a detailed listing of outpatient psychiatric clinics and information on mental health resources in the United States.

Listings include : outpatient psychiatric clinics and their locations, sponsors, geographic areas, age limitations of those acceptable for service, clinic schedules, data about professional staff, state mental hospitals, institutions for mental defectives and epileptics, psychopathic hospitals, veterans administration hospitals, state mental health association, state mental health departments and regional offices of the U. S. Department of Health, Education and Welfare.

PRIVATE SUPPORT FOR MENTAL HEALTH.—A brochure thus titled has been compiled by Jeanne L. Brand, Ph.D., of the National Institute of Mental Health. "Dr. Brand's survey," the preface states, "attempts to analyze the framework within which foundations and other private philanthropic agencies are presently supporting mental health activities." The NIMH, commencing in the fall of 1958, questioned 1,182 foundations and other national granting agencies which might be expected to offer support for some mental health research, training, or service ; the results of the survey refer only to support available on a nationwide basis. This brochure is available from the Super-

intendent of Documents, U. S. Government Printing Office, Washington 25, D. C. (price—35 cents).

EXCERPTA CRIMINOLOGICA.—This new publication, first issue—January/February 1961, provides an exhaustive and up-to-date abstracting service in the field of criminology. It is prepared and published by the Excerpta Criminologica Foundation in cooperation with the National Council on Crime and Delinquency. Articles chosen for abstracting cover the widest possible range. The Board of Chief Editors are Prof. Dr. Th. Würtenberger, Freiburg/Br., Prof. T. C. N. Gibbens, London and Prof. W. H. Nagel, Leyden. Prof. Nagel has been appointed executive editor in cooperation with H. J. Klare, Strasbourg, C. M. Langemeijer-van Schreven, The Hague, and G. Rose, Manchester. The Editorial Board has been drawn from a very wide international field. The editorial and administrative offices are at Herengracht 119-123, Amsterdam, The Netherlands.

Excerpta Criminologica is published bi-monthly; one year's subscription is \$30.00. New York Office: New York Academy of Medicine, 2 East 103 St., New York 29, N. Y.

UNIVERSITY OF MELBOURNE CHAIR OF PSYCHIATRY.—Applications are invited for the above Chair.

The salary will be £5,200 per annum, and superannuation similar to F.S.S.U. in Great Britain will be provided.

Further information and conditions of appointment can be obtained from the Registrar, University of Melbourne, Parkville,

N.2., Victoria, Australia, and applications should reach him by November 1, 1961.

OFFICE OF THE SURGEON GENERAL, U. S. ARMY.—*Colonels Weaver and Glass exchange jobs.* Col. Oswald M. Weaver, MC, has been appointed Chief of the Psychiatry and Neurology Consultant Branch in the Army Surgeon General's office. He succeeds Col. Albert J. Glass, MC, who is now Consultant in Neuropsychiatry to the Chief Surgeon, U. S. Army Europe, the position Col. Weaver held before coming here.

Colonel Weaver received his M.D. degree from the University of Virginia in 1936. Entering on military duty in February 1941, his assignments include Commander of the 81st Hospital Train and Executive Officer of the 74th General Hospital in the European Theater during World War II; Assistant Chief of the Neuropsychiatric Service at the 361st Station Hospital in the Far East Command in 1950-51; Chief of the Department of Neuropsychiatry at Fitzsimons General Hospital, Denver, Colo., 1951-55; Chief of the Psychiatry Service and Department of Neuropsychiatry at Letterman General Hospital, San Francisco, 1955-57; and Consultant in Neuropsychiatry to the Chief Surgeon, U. S. Army Europe since 1957.

The Colonel is a Diplomate in psychiatry of the American Board of Psychiatry and Neurology, a Fellow of the American Psychiatric Association, and a holder of the "A" military specialty rating. The rating is a special honor reserved for those officers who are outstandingly qualified, and have demonstrated exceptional professional ability in their particular specialty.

CIVILIZATION

Two things are clear: there must be a very different civilization or there will be no civilization at all; and the other is that neither the old religion combined with the old learning, nor both with the new science, suffice to save a nation bent on self-destruction.

—OSLER

BOOK REVIEWS

DIE SPAETSCHIZOPHRENIE. By Wolfgang Klag-es. Biographie und Klinik schizophrener Ersterkrankungen des mittleren Lebensalters. (Stuttgart, Germany: Ferdinand Enke Verlag, 1961, VII, 162 pp. DM 25.)

The author follows Manfred Bleuler's notion of late schizophrenia which concerns clinical pictures first observed after the 40th year of life. His non-selected material consists of "fully schizophrenic pictures" which had occurred between the ages 40 and 60. His 53 cases, 38 women and 15 men, were admitted to E. Kretschmer's clinic in Tuebingen between 1953 and 1958. The cases are well reported. The personality and its development are gone into intensively. The main group of 40 late schizophrenics is flanked by a schizothymic border group of 10 and a cyclothymic border group of 3 cases. Practically all the patients belonging to the main group were capable and competent in their professional or vocational work with little private life; tough energy was paired with sensitivity. Activity, craving for success with unmistakable coldness were no less conspicuous than high grade vulnerability. These persons did not have any hobbies.

At the first signs of aging the normal individual looks back critically and tries to catch up in respect to interiorization and maturity. In this respect the author's patients failed, getting into all manner of crises and conflicts.

Their symptomatology is essentially not different from the symptomatology of other schizophrenics. However, the contents of the delusions were found to be closer to the ego. There was a wealth of bodily sensations, or rather mis-sensations.

The course in most instances was acute and relatively favorable in those cases of the main group that had cyclothymic elements. These cases and those of the cyclothymic-pyknio border group came often to full remission.

This is a nice piece of work in which a number of already known observations receive considerable support. The author stresses that there are pre-formed tracks due to the age of the patient along which the development passes. He shares with many of us the notion that "the psychosis can use for its build-up only possibilities which are already there." It would be discourteous and uncautious to argue about some of the author's diagnoses.

There is much said about the structure of the psychosis, but the name of Karl Birnbaum

who wrote a classical book (1923) about this topic is never mentioned. It is also regrettable that the author has not one word to say about the studies of Henri Ey.

EUGEN KAHN, M.D.,
Houston, Tex.

HANDBUCH DER NEUROSENLEHRE UND PSYCHOTHERAPIE. Edited by Viktor E. Frankl, M.D., Victor E. Freiherr von Gebsattel, M.D., and J. H. Schultz, M.D. (Munich and Berlin: Urban & Schwarzenberg, parts 8-20, 1958, '59, '60. Respectively: DM 20, 13.50, 19, 20, 28.50, 20, 19.50, 23.50, 18.75, 17, 13.50, 17.)

The first 7 parts of the *Handbuch* have been reviewed here previously. In Part 8 Bally aims to show how Freud's "idea" of psychoanalysis was originally derived from hypnosis, and around it he developed his theoretical system. Bally does not take sides as to the pros and cons of psychoanalysis. A. Uchtenhagen contributes a chapter on *Zwangsneurosen* (compulsive disorders), in which he attempts to differentiate between the neuroses and the psychoses.

Series 9 deals with some of the analytical schools. Emil Gutheil, the late editor of the *Am. J. Psychotherapy*, discusses Stekel and his deviation from Freud's concepts, and his use of pedagogic methods and suggestibility. Schidder writes about the "Neo-Psychoanalysis" of Schultz-Hencke; his contribution is more outstanding than that of Schultz-Hencke. Alexandra Adler reports on her father's Individual Psychology, indicating the range of the schools of thought which were influenced by Alfred Adler. Her article is particularly helpful. Finally, Heyer summarizes C. G. Jung's psychology and states his opinion that Jung's *Lehre* has not reached the final stage yet, but that his psychology "stimulates development." It is doubtful whether Heyer's view will be accepted by the students of Jung; indeed, the question arises why was not a student of Jung asked to write about analytical psychology.

One of the editors of the *Handbuch*, Victor von Gebsattel, starts off Series 10 with a contribution on "Psychocatharsis." Unfortunately, the subject is dealt with too summarily, without notice of other important contributions on this subject (Grinker (U. S. A.), Spiegel, Shorvon, et al.). A. Friedemann writes about Szondi's *Schicksalsanalyse*, which has found

few students in this country. Ernst Speer's *Kontaktpsychologie* is dealt with by Kihn, emphasizing the important role of the therapist-patient relationship. Speer does not recognize the oedipal conflicts. The last contribution in this Series comes from the pen of Ernst Speer himself: "*Das Erlebnis als klinische Aufgabe in der aerztlichen Psychotherapie.*" The author seems to quote exclusively from the *Lindauer Psychotherapiewoche*, conducted by him; there is no mention of the many researches conducted in Anglo-Saxon countries.

Series 11 is devoted to "Mental Hygiene." Contributions by such early pioneers in this field, as Heinrich Meng, Federn (ego psychology), von Gagem (mental hygiene in love and sex), Helmut Paul (mental hygiene in work, recreation and leisure-time) are offered, and it seems significant that substantial knowledge has been gained by these authors from their familiarity with American literature. Many of these contributions are directed to German general practitioners, who are probably less familiar with mental hygiene principles than are their American colleagues. A particularly scholarly contribution was written by E. Wiesenhuetter. Bovet reports on marriage counseling as practised in Protestant churches in Switzerland, and indicates that such "counseling" saves the country money and mental hygiene clinics from an overload of patients. Of great interest seems to be the paper of the Nestor of Vienna's psychiatrists, Erwin Stransky, who discusses geriatrics in mental hygiene, although he omits the problem of old-age homes and "Golden Age Clubs," which have sprung up, especially in this country in recent years.

Series 12 begins with L. E. Wexberg's (U. S. A.) paper on social workers. Social work as a team-member of the psychiatry-clinical psychology-social work triangle is still largely unknown on the Continent. Therefore, the author concentrates on the United States, where psychiatric social work found its real field, even though England lays claim to this specialty's origin. Wexberg also discusses the rehabilitation of alcoholics, many aspects of rehabilitative methods being the same as in this country. E. Wiesenhuetter discusses the rehabilitation aspects of all handicaps, surveying trends throughout the world and presenting an outstanding and quite comprehensive bibliography, including authors behind the Iron Curtain! Two contributions deal with the last war: Paul writing (probably from his own experience) on "War Captivity" (the medical, psychological and sociological problems), treating such fascinating involvements as the "Dy-

namics of Escape" and "Brainwashing"; and Frankl reporting about his own psychohygienic experiences in concentration camps, in which he shows how relatively "ineffective" was psychotherapy when applied to inmates of concentration camps. Finally, Paul and Frankl together write on "Psychohygiene in Catastrophes," a chapter in which the authors attempt to answer questions which are timely now to every nation, and attach great significance to the experiences of American psychiatrists during World War II.

Series 13 contains articles on child psychiatry and on psychosomatic medicine. Wiesenhuetter speaks on "problematic phases" during childhood, in which there appears neuroses "typical and specific for children." Fixations and impressions have the utmost significance for children and adolescents; from childhood neuroses may result delinquency as well as stuttering and tics. Kehrer discusses psychosomatic problems of the later years, such as the illness of the executive and the psychoneuroses of the "mature" individual. Therapeutically, the author is in favor of "psychagogics" (The psychiatrist as guide rather than therapist). Glatzel reports on neurotic disturbances in the digestive tract and explains many symptoms which previously were not discussed by such authorities as Franz Alexander. Glatzel seems to have so organized his contribution that every practitioner can use it as a ready reference. Christian contributes "Heart and Circulation," examining the *Kreislauf* and its activity on the basis of certain reactions and attitudes of the patient. In another article he speaks about natural and disturbed breathing; he does not distinguish between primary psychological or primary physiological syndromes in breathing difficulties; rather he sees the breathing disorder from a holistic point of view.

In Series 14, the subject of "sleep" is dealt with in two articles. Frankl presents a stimulating casuistic theory and stresses the value of "paradox intentions" during sleep-disturbances. I. H. Schultz applies his *autogenic Training* to sleep disturbances. Frankl in another contribution discusses "psychogenetic disturbances of potency," including many suggestions for treatment based on researches by Stekel, Reik, Schwarz, *et al.* Wiesenhuetter in his article on "Social Neuroses" rejects Oppenheim's theory of the traumatic neurosis and stresses the input of the *Gelegenheitsapparat* (or *deus ex machina*), particularly in the treatment of hysteria. Hirschmann discusses "industrial" neuroses and distinguishes between real and apparent exhaustion. According to Hirschmann, these industrial neuroses are not only of a

negative value, but also can be considered as the "birthpangs of a new era and of mankind."

In Series 15 Bernard Stokvis speaks about psychosomatic medicine and believes that "orthodox psychoanalysis" is the choice treatment. He feels that the problem of psychosomatics should be attacked from the point of view of the "temperament," for it is the temperaments which underlie the receptivity (*Empfaenglichkeit*) to experiences leading to psychosomatic illnesses. Stokvis believes that all psychosomatic illnesses are still in *statu nascendi*. Hofstaetter's "The American Schools of Psychoanalysis" seems to make clear-cut distinctions, particularly for the German reader who hitherto has known little about the schools dissenting from Freud's teachings. Horney, Fromm, Sullivan, Rogers, Rank, *et al.* The author, who stresses his "neutrality," leaves it to the reader to form his own opinion. Victor von Gebattel discusses his own field, anthropological psychotherapy. He states: "Every neurosis, no matter what the syndromes, is usually a disturbance of the attitude of *sich-zu-sich-selber* (or the ego towards itself). From the anthropological point of view, it can only mean that any intention to help *therapeutically* (italics mine) will not be negated."

Series 16 contains "heavy" reading and will be dealt with lightly. Korgner and Polak discuss existential analysis (now very much in vogue in Europe); Frankl speaks of his own "Logotherapy." He believes that the "collective neurosis" is a symptom of contemporary nihilism. While recognizing some of Freud's principles, he thinks that adults can be treated "differently, for example, by a reorientation of the patient toward the world of the senses and of values."

Series 17, in its first part, is one of the most important items in the *Handbuch* as 2 of the editors, Frankl and Schultz, along with 3 other contributors, H. Mueller-Suur, H. Kranz, and R. Siebeck, attempt to define and to classify the neuroses, and to distinguish the neuroses from "psychopathic" syndromes and from the psychoses. But except for Kranz' contribution, "Differential Diagnosis of the Neuroses as differentiated from Psychopathy and from the Psychoses," none of the authors seems to take account of the great strides which have been made by American psychiatry toward a better and more unified classification and nosology of the neuroses and the psychoses. Nevertheless, it seems that some of the APA's researches have seeped through, though but indirectly. On the other hand, the American psychiatrist will be interested in classifications, brought about by von Gebattel's "cyclothymy," Lemke's "vegetative depressions," Lopez-Ibor's

phobia-"thymopathy," Petrilowitsch's "depression of alienation" (*Entfremdungsdepression*), Schulte's "depression of uprooting" (*Entwurzelungsdepression*), Stauder's "bankruptcy of pensions" (*Pensionierungsbankrott*), and many others. Some nosologies, as advanced by Kretschmer, Kolle, and the late Frieda Fromm-Reichmann, are better known in this country; others may be new here. At any rate, Prof. Schultz comes to the conclusion that "the multitude of attempts in the classification of the neuroses proves the inadequacy of any attempt, and the necessity to utilize a nosology according to one's personality, the history of the patient, *etc.*" The volume concludes with two valuable contributions: Schultz writes on the "Neuroses and Human Biology," and E. Wiesenhuetter on the "Sociology of the Neuroses," the latter again carrying the prize for his comprehensive treatment of the subject and an excellent assembled bibliography, nearly 1,000 references from almost all countries of the world!

Series 18 continues the study of the neurosis with regard to its nosology, its *Wesen und Grenzen* of the medico-psychological techniques and of the "psychotherapeutic situation." A. Vetter, for instance, examines the differential way in which the neurosis was treated by Freud and by Klages. Freud's graphic picture is illustrated by the "moralistic super ego" leading to the ego and from the ego to the instinctual id, whereas Klages has but two steps, the ego (or the *Willensgeist*) and the subordinated *Leibseelisches Leben* (somatic-psychic life). W. Braeutigam and P. Christian seem to divide (perhaps, artificially) the "goals" of psychotherapy between the various schools. A very important section deals with language as a means of communication. This aspect is currently subject to more discussion and examination on the Continent than in this country where the significance of semantics has escaped many of us, and not only in psychology and psychiatry! The balance of Series 18 is devoted to a detailed discussion of tests and statistics.

Series 19 contains, in the main, contributions by various well-known analysts and psychiatrists on the subject of training and teaching. J. H. Schultz discusses the general nature of educational techniques in the teaching methods for psychiatric students as well as, in another article, the problems of lay analysis. W. Kemper's suggestions and evaluation of training in psychoanalysis is, perhaps, one of the best this reviewer has seen and, in the main, corresponds with many American sources, particularly the voice of the APA. He is sharply contradicted

by Ernst Speer's article on "Psychotherapy practised by the layman." Whereas Kemper recognizes the practice of non-medical psychotherapists and presents detailed suggestions to control such practice and safeguard the public, Speer, on the other hand, labels all Ph.D.'s as frauds and quacks. Speer's position is unsupported and at least one editor has disapproved of it (in writing to this reviewer). Prof. Frankl has also disowned Speer's article and has left it to this reviewer to state so. Speer's otherwise fine contributions seem to be obscured by this unhappy contribution to the *Handbuch*. It seems significant that none of the other contributors side with Speer and that the editors have seen fit to have 5 authors write on the subject of lay analysis and non-medical psychotherapy. Whatever can be said of this Series, there is no lack of frankness or shying away from controversial issues and, therefore, the editors ought to be warmly commended for their courage and enterprise.

Series 20 offers but two articles: W. Ritter von Baeyer writes on "Neuroses, Psychotherapy and Legislation," and W. Kemper on "Basic Rules for the Psychotherapeutic Practice." Kemper's article is on a high level, makes for easy reading, and offers excellent material for ready reference for numerous details, such as appointments of patients, books in the doctor's office, magazines in the waiting room, telephone contacts, etc. Von Baeyer speaks of the "criminal impulse," its symptoms, and its legal implications. The latter are in accord with the German Criminal Code. Many implications would apply to our courts likewise, and many case illustrations indicate that German psychiatrists seem to work under similar handicaps (lag of progressive legislation for dealing with offenders) as do their American colleagues.

Summing up, the present 20 parts (constituting 3 of 5 contemplated volumes) bring to the reader the best thinking and research and practice of neurology and psychiatry to date. While it is understandable that not all contributions are equally high in standard and performance, it is this reviewer's opinion that, within given limitations only once in a life-time an enterprise is completed as satisfactorily and comprehensively as this *Handbuch*. It should serve an entire generation of psychiatrists on both sides of the Western Hemisphere as an excellent tool in their daily practice, in their teaching, and in their research. If a generalization may be permitted, German *Gruendlichkeit* and striving for *Universalitaet* seem to have been realized here.

HANS A. ILLING,
Los Angeles, Calif.

INSTITUTIONAL NEUROSIS. By Russell Barton.
(Baltimore: Williams and Wilkins Co.,
1959, pp. 52. \$2.50.)

Russell Barton of Shenley Hospital, St. Albans, England produced a brochure of 52 pages entitled, *Institutional Neurosis* depicting what he sees as the result of deprivation suffered by patients in mental hospitals. He defines institutional neurosis as follows: "This is a disease characterized by apathy, lack of initiative, loss of interest, especially in things of an impersonal nature, submissiveness, apparent inability to make plans for the future, lack of individuality and sometimes a characteristic posture and gait." Doctor Barton writes, "I claim no originality for the ideas presented; my purpose is to try to arrange them in an orderly manner so that they are more easily understood, more readily accepted, and more systematically treated." Indeed the only unique point is the attempt to develop a disease entity. The brochure itself points out with careful detail the system of living generally in vogue in the larger mental institutions. It properly should be read by all those who have the responsibilities for caring for patients, especially in a more or less custodial or long-term situation. It can well be used as a check list of habits, procedures, and traditions in patient care that may be harmful to the patients. It is good reading for all those who have such responsibilities.

HARRY C. SOLOMON, M.D.,
Commissioner,
The Commonwealth of Massachusetts,
Dept. of Mental Health.

THE ENCYCLOPEDIA OF THE BIOLOGICAL
SCIENCES. Edited by Peter Gray. (New
York: Reinhold Publishing Co., 1961, pp.
1119. \$20.00.)

This volume, excellently printed in double column, contains, I have calculated, about 1,200,000 words. The average novel of about 80,000 words costs \$5.00. At that rate this book should cost \$75.00. But it doesn't. It costs \$20.00. It is, of course, a bargain at the price, and, editor, publisher, and contributors are to be congratulated upon its appearance. It covers the whole realm of biology, including most of the outstanding figures in the history of the science who have contributed to its development. (Humboldt's name is thus spelt, by the way, and not as printed in the book, and Fallopius was never a student of Vesalius.) A few minor errors are unavoidable in a work of this size. There are 800 articles and

almost as many contributors. The book should establish itself as the standard work on the subject. The quality of the articles is, in general, excellent and authoritatively written, and some of them, like the article on population genetics, are small masterpieces. For the reader desiring an up-to-date reference work on virtually every aspect of biology, written briefly and clearly, this volume is to be highly recommended.

ASHLEY MONTAGU, Ph.D.,
Princeton, N. J.

CURRENT THERAPY—1961. Edited by *Howard F. Conn, M.D.* (Philadelphia and London : W. B. Saunders Co., 1961, pp. 806. \$12.50.)

The 13th annual edition of this highly successful book on therapeutics follows the plan of its predecessors : experienced physicians describe the methods which they use in treatment. The contributions of more than 300 doctors for the most part deal with diseases, but some common symptoms such as headache and diarrhoea are also discussed.

The psychiatrist will find sections devoted to neurosis, schizophrenia, depression, manic-depressive reactions and delirium which cover familiar ground. Perhaps more valuable for him will be some of the sections referring to therapeutic problems commonly associated with mental illness such as cirrhosis, narcotic addiction, epilepsy, neurosyphilis, nutritional deficiencies and various poisonings which receive extended coverage. Therapeutics has become a vast subject which can be presented in a variety of ways. This book might be classified as highly pragmatic, not concerned with pharmacology as an academic subject and not emphasizing the controversial aspects of some treatments. It unquestionably is a useful and reliable guide to the management of most conditions which a physician might encounter.

W. B. SPAULDING, M.D.,
Toronto, Canada.

EDGAR A. POE. By *David M. Rein.* (New York : Philosophical Library, 1960, pp. 134. \$3.75.)

It is no secret that much, if not most, writing that may be called literary is more or less autobiographical. In discussing the life and works of Edgar Allan Poe, Mr. Rein (Associate Professor of English, Case Institute of Technology, and author of *S. Weir Mitchell as a Psychiatric Novelist*, 1952) documents thoroughly this point of view. He agrees with Baudelaire, who early recognized in Poe a

kindred spirit, that in his constant preoccupation with scenes of horror Poe revealed a dominant masochistic strain so characteristic of himself. Said Baudelaire, "I found poems and short stories which I had conceived, . . . which Poe had been able to organize and finish perfectly . . . I was shocked and delighted to see not only subjects which I had dreamed of, but *sentences* which I had thought and which he had written twenty years before."

As Professor Rein amply demonstrates, Poe was his own worst enemy. In the development of his personality from youth time on there was no conformity to what might be called a normal or average or wholesome type. On one side there was brilliant if often sordid play of imagination and high poetic gifts ; on the other morbid restlessness and inconstancy and shocking irresponsibility—an overplus of intellectual qualities with the imbalance of the immaturity of a child, so often characteristic of the genius.

The present volume is useful as a concise commentary on many of the poems and stories, especially as illustrating the author's thesis that in his writings the poet repeatedly pictures himself both physically and in his overpowering emotional states and crises. Poe lost his mother at the age of three, and that this loss had a significant effect on his life is easy to understand without the help of John Bowlby, whom the author, perhaps needlessly, quotes. Throughout his short life Poe was to an extraordinary degree dependent upon the love and care of women, and his impulsive longing was expressed in varying phases as want of mother love, of the love of a wife, or of a devoted sister as represented by his child-wife, Virginia Clemm. In his letters he repeatedly expressed himself as desperately in need of affection and support, even declaring that he cannot go on without assurance of the devotion of one or another of the women who figured prominently in his life.

One can hardly disagree with the author that the dominant influence in Poe's unsettled career was the unhappy issue of a youthful love which at the time was a mutual attachment resulting in an engagement to marry. The poet seems never to have been reconciled to this loss which may have played a part in his subsequent alcoholic habits and the desperate and disordered mental state he often referred to in his letters. Just before his tragic death he paid a visit to the one he had first chosen to be his wife. In the long interval she had married the man of her father's choice, not her own, and was now a widow. But it was too late to go back and take up life again where it had been turned awry in their youthful age.

That tragedy may well be immortalized in one of Poe's most beautiful poems, *Annabel Lee*, which can hardly be read without tears.

C. B. F.

THE DISEASE CONCEPT OF ALCOHOLISM. By E. M. Jellinek. (New Haven: Hillhouse Press, 1960, pp. 246. \$6.00.)

This book starts with historical material concerning the concept of alcoholism as a disease. The discussions and arguments both *pro* and *con* are given in an interesting manner. Members of the American Psychiatric Association will be interested to hear that Benjamin Rush and Samuel Woodward were among those who advocated the medical approach to alcoholism. Benjamin Rush thought of inebriety as an illness and Samuel Woodward, the first superintendent of the Worcester State Hospital, suggested special institutions for inebriates.

The author goes into considerable detail in trying to define what is meant by the term disease. He quotes medical dictionaries to show that disease is defined as an illness or sickness. He believes, however, that the word illness is more acceptable to the general public. He concludes: "It comes to this, that a disease is what the medical profession recognizes as such. The fact that they are not able to explain the nature of a condition does not constitute proof that it is not an illness." He likewise points out "that the medical profession has officially accepted alcoholism as an illness, and through this fact alone alcoholism becomes an illness, whether a part of the lay public likes it or not, and even if a minority of the medical profession is disinclined to accept the idea."

The author also discusses what is meant by the word definition. He then defines alcoholism as "any use of alcoholic beverages that causes any damage to the individual or society or both. Vague as this statement is, it approaches an operational definition." He speaks about the "species of alcoholism" and describes Alpha, Beta, Gamma, Delta and Epsilon Alcoholism.

There are interesting discussions of the differing viewpoints about the use of alcohol, of the various legal arguments regarding the alcoholic receiving compensation for a disease and of the attitudes of many of the large corporations and the labor unions toward the question of alcoholism as a disease.

The author quotes from a great deal of the literature concerning the psychological and physiological formulations of addiction. Special attention is paid to the withdrawal syn-

drome and the concept that the alcoholic becomes dependent upon alcohol as the opium addict becomes dependent upon opium. He concludes that it is now well established that there is a physiological addiction to alcohol with physical withdrawal symptoms whenever the alcoholic either reduces greatly or stops completely his use of alcohol. He includes considerable material on the concept of delirium tremens and convulsive reactions being withdrawal symptoms.

These comments will give the reader some idea of the material to be found in this book and the attitude of the author. The book is an excellent and carefully prepared discussion of the writings that bear on the subject. The reviewer unhesitatingly recommends this book to anyone interested in the problem of alcoholism.

MOLECULES AND MENTAL HEALTH. Edited by F. A. Gibbs. (Philadelphia: J. B. Lippincott Co., 1959. \$4.75.)

This is, in a sense, a monograph which deals with 2 separate but related problems in that the discussion centres around disturbances of brain function with biochemical determinants. It is a report of 2 conferences held in 1958 under the Auspices of the Brain Research Foundation. The volume was edited by Dr. Frederic A. Gibbs. Part I deals with amines in relation to brain function and behaviour. The speakers were men of experience in the field and the discussants, participants and guests were equally able men and women. The problems of ceruloplasmin and serotonin and the ergot hallucinogens were presented and discussed. Probably the most important feature of the book is the frank and pointed discussion which is recorded. Undoubtedly some will feel it could have been even more frank as much of the material presented is in need of the most searching criticism by chemists and psychiatrists. There is still a great need for controlled investigations in this field with an experienced psychiatrist as a separate somewhat disinterested member of the team. Alterations in human behaviour simply have to be studied in terms of sequence of events and not in cross sections and this aspect of the work is often not adequately developed by those interested in what has been called psychopharmacology. Part I is recommended to all those interested in the field of psychiatry.

Part II deals with the subject, infantile spasms and their E.E.G. counterpart—hypsa-

rhythmia, which is of increasing interest to psychiatrists, neurologists and pediatricians. Every angle of this serious disorder of brain function was considered, including pathologic features characterized by spongy degeneration of the brain. This is a special problem in cerebral and cerebellar degeneration of infants and children. It was well reviewed at the conference and the discussions are highly recommended to all interested. Causes, mechanisms and treatments were considered with frank discussions of each aspect. It is an excellent symposia.

In summary, this book has much to commend to all interested in brain dysfunction from a biochemical standpoint; hence, of special interest to psychiatrists and neurologists.

ALLEN A. BAILEY, M.D.,
University of Saskatchewan.

A MANUAL OF PSYCHIATRY. By K. R. Stallworthy. (Christchurch, New Zealand: N. M. Peryer Ltd., 1959, pp. 365.)

This book, a fourth edition, originates from the pen of the Medical Superintendent of the Takani Hospital, Te Awamutu, New Zealand. The preface dated January 1959, states his aim "To give the medical student, general practitioner, or nurse a factual account of what is likely to matter to them." However, the book reflects the vast practical experience of the author in a distant country and to an American psychiatrist who is willing to read between the lines the book can be a fascinating source of information about residual differences in a technical field where ever more efficient communications keep driving all the world toward a dead-level of universal similarity.

To achieve his goal the author has had to expand his subject matter to include a more heterogeneous content than what would be found in similar American texts. This includes such items as mental deficiency, a considerable amount of neurology, epilepsy, some syphilology, acute delirious states, as well as psychodynamics, descriptive psychiatry, legal aspects, administrative psychiatry and somatic therapy.

All this has been compressed into 267 crisply written pages filled with simple direct definitions aimed at his chosen audience. The style is concise and the point of view conservative even as to terminology which will sound strange to most American professionals of recent vintage. Among such terms are "toxins" which are invoked as a cause of mental abnormality, "melancholia," "weak-mindedness," "G.P.I.," "tranquillisers," "delirious mania," "chronic mania," "dement," "insane," "sleepy

sickness," "paraphrenia," "schizophrenic dementia," and "demented paranoid schizophrenia."

Differences of practice as well as terminology seem to be reflected in the text. One finds a full page on hydrotherapy, 2 pages on malarial therapy with indications that a strain of inoculation malaria is still kept active, almost 5 pages on leukotomy, 7 pages on insulin coma, 10% on electric shock, and only 2½ pages on tranquilizers. Allowing for the fact that this was written about 3 years ago there still appears to be less dependence on drugs than one might find in this country. The author states "Such drugs relieve certain symptoms, sometimes; they do not cure." On the other hand he states with regard to chlorpromazine "It acts within a few days if at all," and continues, "but those who are no better from 150 mg. a day are unlikely to benefit from more." Doses apparently range up to 250 mg. per day.

There is a lack of discussion of the newer antidepressants which may be explained by the date of the writing of the book. Certain aspects of psychiatric organization such as family care are apparently not important. On the other hand the general attitudes toward hospital organization and community participation seem to be very similar to those generally held here.

The similarities outweigh all the differences which can be found. The section on alcohol reveals an extensive experience essentially similar to our own although heroin is but "another dangerous drug of addiction" its only description in an entire chapter. The open ward philosophy is a part of standard hospital practice and the text reveals an increasing importance in problems of child psychiatry and psychiatry of the aged.

All this may be of interest as background reading for students, in spite of differences in nomenclature but a trend of broader interest may be the pattern of participation by the general practitioner, one of the three main groups toward whom this book is directed. This is reflected in the fact that new sections were added to the present edition on tranquilizing drugs, psychiatric disturbances in childhood, senility and pregnancy and on personality reactions to physical disease. Perhaps the developments with regard to "G.P.I." represent a shadow of things to come. "The treatment of G.P.I. now involves primarily adequate dosage with penicillin, perhaps a million units a day for a month." Who can deny that with these few words the practitioner moves into a treatment position unreached by the specialist

when diagnosis and treatment were more complex. A similar emphasis on psychiatry in general practice is reflected in the 5% pages of description of puerperal psychoses and in the treatment of another practical problem, namely, head injury.

In summary, this book may be said to contain much food for thought as well as background reference material for students.

HENRY BULL, M.D.,
Dept. of Mental Hygiene,
Albany, N. Y.

LOWIE'S SELECTED PAPERS IN ANTHROPOLOGY.

Edited by Cora Du Bois. (Berkeley and Los Angeles: University of California Press, 1960, pp. 509, \$10.00.)

Robert H. Lowie (1883-1957) was one of America's most distinguished anthropologists. The present volume reprints some 33 of his most significant contributions to the anthropological literature, and together they constitute a rich cornucopia indeed. Those contributions range from kinship and social organization, psychology and sociology, race, totemism, and history, to literature, aesthetics, and language. It is a delight to participate with a first-class mind in the exploration of human nature in a volume which is a fitting memorial to a pioneer anthropologist.

ANILKY MONTAGU, Ph.D.,
Princeton, N. J.

AUTOMATION, CYBERNETICS AND SOCIETY. By F. H. George, Ph.D. (New York: Philosophical Library, 1959, pp. 280. \$12.00.)

The onset of the industrial revolution marked the end of an epoch and ushered in the modern world, which although it has provided greater material wealth, and comfort, has done so by degrading the dignity of man. Technology, like the broom of the sorcerer's apprentice, has escaped from control and gone on a rampage. The next phase of the industrial revolution, known as automation, has suddenly confronted mankind and threatens to reduce so-

ciety to chaos. The development of automation has inspired the expounding of communication theory, and exploring its ramifications and implications. Since the direction and control of both man and machines depends upon communication, the guidance and control of communication, in the broadest sense, is vital for the welfare of mankind. This guidance and control is known as "cybernetics."

As an academic science, cybernetics can be defined as the science of communication, yet it implies the integration of an intercommunication between biology, the physical sciences and mathematics on the one hand with engineering, the social sciences, and economics on the other. If the integration is adequate the present phase of the industrial revolution will be accomplished without a major social upheaval.

In this book, Dr. George has explored the problems facing society, and found that the major hurdle is control; communication is the fundamental instrument of control. If society is able to direct technology, then the full measure of human dignity will be restored to man, and he will enjoy the wealth of his technological advances.

The volume is divided into 3 unequal sections each of which deals with one aspect of cybernetics. Each section can be read independently of the others, yet forms an integral part of the whole. The first part (45 pp.) deals with the social and scientific milieu which has produced the present unstable situation. The next 150 pages deal with the established scientific background of cybernetics and automation, while the last 75 pages discuss the application of these principles to the social scene.

It is a luckily written volume, which presents the argument in a reasonable and orderly fashion. In spite of this it is a book that demands close attention, for it presents many concepts that will be new to most readers, yet the result is worth the effort for the ideas are provocative and the implications spread into all aspects of life.

Toronto General Hospital,
Toronto, Can

THE ACADEMIC LECTURE

THE HEURISTIC ASPECT OF PSYCHIATRY¹

SEYMOUR S. KETY, M.D.²

For years I thought I knew exactly what should be said to this important body of psychiatrists if one had the unusual opportunity of pontificating before them. Now that your distinguished president and my kind preceptor has given me that opportunity, I falter. In these Fellowship Lectures a notable series of scholars have variously justified, judged, jeered, jugulated, and on one occasion even jilted you (in a remarkably cogent demonstration of the Uncertainty Principle). The lecture today can be traced directly to a meeting in the spring of 1951 with Robert Felix, your president, who excited me to leave a laboratory of cardiovascular physiology and to join a great institute he was building. For ten years I enjoyed the privilege of participating in a unique program of psychiatric research which was developed in the atmosphere of scientific freedom and sympathetic support with which he endowed it. It may be of some interest to read the impressions of one with such a background who has willingly and not unsympathetically wandered into psychiatry. I need not point out for this audience that these are ruminations based upon my observations but also upon my biases.

Much has been said of the relative lack of research interest in the field of psychiatry, compared with the strong motivation towards therapy among its practitioners and those who come for training. It may well be that this perception contributes to the position of surprisingly low prestige which psychiatry occupies among the medical specialties in the eyes of the medical student, at least as a recent survey in 3 schools indicates⁽¹⁾. If it is true that a vigorous motivation towards research has

only recently entered the field of psychiatry in contrast to some of the other branches of medicine, it is easy to see why.

There are fields of human endeavor where the initial motivation and achievement have been in the acquisition of fundamental knowledge, which only later has led to application. The demonstration of induced magnetic fields about an electrical conductor occurred before the development of the electric motor; basic knowledge of atomic structure was at hand before the possibility of fission and the release of atomic energy could have been realized. There are other fields, historically, where application has come first, to be revised, substantiated and improved upon by subsequent inquiry and accomplishment. Man made fire before he knew about oxygen and built bridges before he learned of Hooke's Law.

As opposed to the natural and the physical sciences, medicine and psychiatry, especially, are disciplines motivated to a large extent by a sensitivity to human suffering. It is easy to see how such a polarization might have distorted the orderly growth of these disciplines from the simpler pattern which cold logic would have preferred. The physicist, the chemist, even the neurophysiologist can be patient—building small but hard facts one upon the other for a purpose in which he has faith but whose ultimate outcome he may not live to see. The neutron did not come begging to be discovered, but the patient suffering from disease or troubled or incapacitated by conflict cannot wait. The physician to whom he turns for help can hardly say, "Come back in three centuries or so when we may really understand these things."

Every branch of medicine has begun with therapy; only later and gradually were the basic and clinical sciences drawn in. We have seen in their order anatomy and pathology taking an early place as important medical sciences only 300 or 400

¹ Read at the 117th annual meeting of The American Psychiatric Association, Chicago, Ill., May 8-12, 1961.

² Henry Phipps Professor and Director, Dept. of Psychiatry, Johns Hopkins University.

years ago. There was a long lag even after Harvey's notable achievement before physiology became recognized as a science which had contributions to make to medicine. Bacteriology struggled long to gain a foothold, then repaid its acceptance with a series of contributions to the alleviation of human illness which are still unmatched. Biochemistry, within the recollection of many of us, entered the field in strength and today is at a well deserved peak of acceptance, achievement and promise. The behavioral sciences have only recently begun to make their way into the medical curriculum and into the recognition of the physician as sciences basic to medicine. They have already begun to make remarkable progress but their most exciting potentialities and contributions remain ahead of them. Lagging far behind the development and recognition of the basic sciences, the various branches of medicine have marched from a therapeutic art to a clinical science. Much of this progress has occurred within our lifetime. The *materia medica* which our fathers learned, aside from a relatively few agents like digitalis and the hypnotic drugs, was elaborately specious, developed before modern pharmacology and perpetuated by the peculiar selectivity of uncontrolled clinical experience.

As recently as 52 years ago a small group of Young Turks, impatient with the impressionistic and anecdotal nature of medicine, organized the American Society for Clinical Investigation whose aim was to be "the cultivation of clinical research by the method of natural sciences; the unification of science and the practice of medicine; the encouragement of scientific investigation by the practitioner, and the diffusion of a scientific spirit among its members." Thirty-five years ago, in 1924, the Society first began the publication of its *Journal of Clinical Investigation*. On the first page of the first volume of that journal appears its first and last editorial, a noteworthy paper by Alfred E. Cohn, entitled "Purposes in Medical Research"(2). A study of that paper gives one a sense of the revolution which was taking place in medical thinking, no farther away than yesterday, and a taste of the judicious zeal which motivated some of its leaders. Most interesting of all one

can see in those pages an anticipation of the same renaissance which one feels is taking place in psychiatry at present. I should like to quote some of the passages:

We have . . . for some time been inquiring whether medicine is entitled to be called a science. To us the answer to this question is clear and unequivocal. It is clear because of the nature of the case. The phenomena of interest in medicine are the phenomena of disease as these are manifest in affected persons. They are phenomena which exist as concrete entities in nature, they are indivisible and they fall within the province of no other inquiry. They constitute the proper concern of medicine. Nor are the phenomena of disease the combination or resultants merely of other forces. They are not the resultants of forces known in physics or chemistry, or in physiology or mathematics, nor the resultants of any combination of these. Rapid and shallow breathing, for instance . . . remains a unique phenomenon, even though the terms in which it is characterized are anatomical or physiological or chemical. Anatomy or physiology or chemistry may supply the methodology for analyzing its occurrence, but the occurrence is something apart from and over and above the factors into which it can be resolved.

There is another passage, remarkable in its applicability to the present ferment in psychiatry:

This, then, is the task which academic medicine in the United States, now become self-conscious, has set itself; it is the task of Clinical Investigation. Its business involves a legitimate interest in learning as well as a means for furthering methods which lead to the cure of disease. It is vitally concerned in the success of both these projects. . . . *We must appreciate the fact that perhaps there is no single road of salvation open; search for the single road has often led hunters far afield.* (italics mine)

To give substance to ideas like these is the purpose which lies behind the work of the university clinics which are being founded in many parts of our country. They mean to take on new functions. Those on which they lay emphasis indicate the adoption of a wider interest in the problems of concern to medicine. In addition to the traditional responsibility for teaching, they avow the desire to contribute to an increase of knowledge. They are drawing to themselves new men, trained in a new way; they are being supplied with

new hospitals properly equipped with laboratories in which to pursue what Bernard called the *observation provoquée*.

Those forthright words reflected a development in medicine which contributed I am sure to the burgeoning of medical research to an unheralded state of acceptance, activity, and productivity. I have little doubt that a similar course, accelerated now by the unprecedented public support which it is receiving, lies ahead for psychiatric research; in fact, we are already well embarked upon it.

This ferment in psychiatry has a rich mash. Even a casual glance at the accomplishments in the basic disciplines of psychiatry in the past decade gives one cause for some gratification and optimism. The electron microscope, only recently applied to the nervous system has begun to outline the structure of what heretofore has been an operational concept—the synapse, and to establish the precise localization of certain neurosecretory elements within the cell(3, 4). Embryology in association with immunochemistry has very recently seen the development of growth promoting substances with specific action upon nervous tissue and the ability specifically to inhibit the growth of certain nervous tissues by their antibodies(5). Anatomy, joining hands with physiology, psychology and even sociology, has advanced our knowledge of the functional organization of the brain and its relationship to individual and social behavior(6, 7). Great strides have been made in the mapping of the human cerebral cortex and in the relationship of cortical physiology to subjective states and memory(8). Studies in the limbic system have elucidated some of the physiological substrates of affect, emotional state and sexual behavior(9). Highly specific chemoreceptors in the hypothalamus have been discovered capable of triggering appropriate sexual behavior in response to sex hormones(10). The reticular system and the more recently described sensory feedback systems have provided new concepts of the control of attention and the modulation of sensory input(11, 12).

In the past 10 years the field of neurochemistry has gained recognition and status

as a discipline. It has learned much about the energy metabolism of the brain and its correlation with mental state(13). The presence of norepinephrine and serotonin and other biogenic amines differentially distributed in significant fashion within the brain has been discovered and considerable research invested in their role in behavior and in the action of a number of psychotropic drugs(14, 15). Much has been learned of the synthesis and degradation of epinephrine, the first of the chemical mediators of mental state to be described(16, 17). This information has permitted the study of the metabolism of that hormone in schizophrenia(18) and will make possible measurement of its endogenous production in a variety of clinical conditions and disorders. Protein turnover and metabolism have been examined in the brain and the beginnings of support are appearing for the interesting hypothesis that in the protein molecule may lie some of the answers to the riddle of memory(19).

In the basic behavioral sciences there has been much activity of interest to psychiatry during the past 10 years. The imprinting process, the basis upon which young animals acquire crucial behavior patterns from early experience on a genetically prepared substrate has broadened our concept of instinctive behavior(20). The appetitive and aversive centers in the brain may have important significance to the physiology of affect(21). The widespread use of the conditioned reflex and the technique of operant conditioning has opened wide the study of some of the fundamental aspects of learning, motivation, and drug effects(22). In other branches of medicine the development of an animal model of a human disorder has frequently served as the spearhead for rapid progress toward its understanding and alleviation. Animal models of neuroses, anxiety states, and psychosomatic illness have now been described(23, 24) and the recent paradigms of maternal protection and deprivation in monkeys(25) will provide hypotheses for the more complex phenomena in man. Hilgard(26), Mirsky(27), Kubie(28), and Benjamin(29) among others have masterfully reviewed the evidence from basic research both in animals and man which support some of the funda-

mental assumptions of psychodynamic theory and which will serve as the bases for further heuristic hypotheses.

Although one tends to highlight those findings which seem to have greatest possible relevance to psychiatry, there are many more contributions of possibly greater moment whose relevance at the present time is obscure. I believe it was Virchow who said 100 years ago that biochemistry had little to offer at that time to pathology or to medicine, but he was quite sure that the time would come when it would.

When we turn to mental illness, it appears that the practical accomplishments of research in the recent past have been few and the progress disappointingly slow. The accumulation of fundamental information goes on for a long time before it is possible to fit together the essential facts in a hypothesis which requires an equally long time for its evaluation. When we recognize the utter complexity for the field of human personality and behavior, normal as well as disordered, we are forced to assume that the stepwise progression toward an understanding of these phenomena will be slow indeed; only rarely and by the sheerest stroke of good fortune will there come a surge of material progress. Aside from paresis, the mental syndrome of pellagra, certain other toxic and metabolic psychoses, and phenylketonuria, the biological sciences have not yet contributed significantly to the understanding of etiology, and these achievements were accomplished some time ago. Other than that we have only hypotheses for the etiology and the pathogenesis of the mental disorders which continue to plague us.

Interestingly enough we tend to forget about the important achievements which have been made, such as those which I have enumerated, since once a mental disorder is reasonably well understood and has had its etiology and pathogenesis adequately explained it ceases to be part of psychiatry, as if we insisted that only the mysterious ailments were psychiatric in nature. Or is it that the training of so many psychiatrists of this generation is so predominantly in psychodynamic theory to the exclusion of the biological and even the social and psychological sciences that he feels uncertain

or aloof in the management of disorders where the important factors in etiology are biochemical or microbial, and relegates them cheerfully to neurology or to medicine? This would be unfortunate, if it were true. We need no longer today reiterate the thesis that the roots of psychiatry are just as firmly planted in biology as in the sciences which deal with experience and human relationships. If, on the basis of preconceived notions or the bias of particular training, we chop off one of these major roots, can we expect the tree to flourish? To state this position more clearly, I have sometimes employed a little diagram of the mechanisms of human behavior (Fig. 1).

Not all of the parts of this drawing are based upon established fact, and I expect that in the next few hundred years there will be some revisions in it. Yet I cannot help but feel that it *represents* the actual situation even though it describes it inaccurately. Human behavior, especially in those aspects which make it peculiarly human, has two important and absolutely essential components. There is the machinery and there is the incoming and stored information based on experience. There is no single discipline, unless it be psychiatry itself in its broadest sense, which is capable of describing and comprehending both components (30). In any disorder of behavior the so-called "lesions" are in both of these components, although it is possible for the primary defect to be in one or the other. Thus in the three conditions which I have already mentioned, paresis, pellagra, and phenylketonuria, the primary defect is in the machinery (if we confine our attention to the afflicted individual and for the purposes of this argument neglect a more fundamental lesion in society). I have no doubt at all that there are other disorders of personality and behavior where the primary disturbance has been in experience reflected in the stored information; and similarly no doubt that still other disorders require defects in both of these spheres. Although lesions have been postulated for many disorders in each of these areas, I think it is fair to say that none of them has been demonstrated with the rigor and clarity which characterize the three conditions I have mentioned. The

FIGURE 1
The Mechanism of Behavior (Diagramatic)

"chemical lesion" of schizophrenia and the specific aspect of parental or family influence which are "schizophrenogenic" have in common the fact that they are both hypotheses. But they are heuristic hypotheses and are responsible for considerable current research.

There is need in such a scheme for both analytic chemistry and psychoanalysis, using the latter in its research rather than its therapeutic sense. The neurochemist can, if he is sophisticated, look for particular chemical components and study their metabolism in the brain. Before he was able to do that, however, it required a Thudichum to analyze the brain as a whole to the best of his ability, using the techniques which he had available and trying to introduce a minimum of denaturation or distortion to the compounds which he isolated, so that he ended up with a weighted analysis of the brain. In the same way the psychoanalytic process in its purest form can be looked

upon as a sort of information retrieval. Of course one can formulate specific questions and, using techniques of modern sociology and psychology as well as the examination and interview of the skilled psychiatrist, obtain responses to specific questions. But in order to know what questions to ask it would seem to be of fundamental importance to have some approximation to a total analysis of the object of discourse, be it brain or information, be its components "free" and "bound," or "conscious," "preconscious" and "unconscious." It would also be useful to know the relative weightings of these components in the whole. To some extent a non-directive psychoanalytic technique fulfills these criteria, at least it does so better than any other technique which we have today, especially if it recognizes and makes some compensation for the distortions introduced by the analytical procedure.

I seem to hear murmurs of objection to

this elementary formulation from two camps. The one rebukes me for having idealized the psychoanalytic process. They say that I have ignored the incrustation of dogma, authority, circular reasoning, and self-fulfilling predictions which mark the psychoanalytic school. There are others who will say that this reduction of the psychoanalytic process is childishly naive, has discarded the rich contributions of psychodynamic theory, the values of transference and counter-transference and other important aspects of interpersonal relationships which are inextricably bound to the psychoanalytic process, or that I have stripped and dehumanized "the most insightful contribution to our understanding of human nature in the history of humanity" (31). To whatever extent these allegations are true, I have provoked them deliberately, in order to find an essence in psychoanalytic process which can be accepted by the most critical scientist as a minimum achievement or desideratum.

I must also confess to a little impatience with the recurrent debate on whether Freud was a pretender or an intellectual superman whose theory must, *ipso facto*, form the basis of modern concepts of human behavior; whether his followers are specially anointed with unique insights into understanding the human mind, or a group of benighted, doctrinaire and unscientific partisans. Such *ad hominem* arguments have no place in the forum of science. I prefer to look at Freud with a certain amount of detachment and in the context of his time. Borrowing heavily from the work and opinions of many others (as we all do and should), he elaborated a theory, or more properly a group of theories, and against much opposition promulgated them with such conviction and zeal that it broadened the field of psychiatry and revolutionized the concepts even of his adversaries. The validity of his particular theories is not nearly so important as the cogency of his point of view nor as the probability that he contributed substantially to introducing into the discourse on human behavior the idea of the importance of unconscious elemental drives and experiential factors, and led the movement which was, to a large extent, responsible for adding the information component to the mechanism of be-

havior. He did this at a time when the consensus of thinking was emphasizing the overriding importance of anatomy and pathology, when constitutional factors were thought capable of explaining all aspects of behavior from chorea to criminality.

It is nevertheless true that most of these theories have not yet had the opportunity and advantage of testing and validation by the accepted methods of science. As a gratuitous personal opinion, I doubt whether Freud's theories will eventually turn out to be the most complete or valid explanations of human behavior. If they did it would be a really unprecedented achievement. Galileo invented a telescope, made some observations on free fall, and promulgated his own opinion and that of others that the earth revolved about the sun. Newton found some important generalizations in the simple motion of material objects and derived a mathematical expression for the force of gravity. William Harvey, building upon the work of others, postulated the circulation of the blood. These great human achievements would be surpassed by far if it were true that Freud, on the basis of his own knowledge of anatomy, physiology and the behavioral sciences, or even upon all that was known in his time, could have developed a theory which explained even a significant segment of the fantastic complexity of human behavior. To whatever extent his theories will be substantiated, modified or refuted by scientific evidence which is now beginning to be acquired, his contribution to psychiatry will remain a permanent and substantial one.

Many reasons have been given which purport to explain why psychiatric research, especially that which is designed to test psychodynamic theory, is different from research in other branches of medicine or science, and why the usual rules of scientific evidence cannot be applied to it. I remain unconvinced that psychiatry is a field apart from other areas of scientific discourse. Although I recognize the cogency of many of these arguments, I would prefer to think of them as possible pitfalls or as difficulties, greater in this field than in others, which must be taken into consideration and must somehow be overcome.

There is the strong feeling in some quar-

ters that research and good therapy are incompatible. It is felt that regardless of the validity of the hypotheses or interpretations, it is therapeutically important that the patient believe them implicitly. It is further felt that doubts and skepticism on the part of the therapist which are admittedly the important qualities of the investigator would somehow be communicated to the patient, with a resultant loss in his confidence and in the efficacy of the therapy.

While all of this may be true there is no acceptable evidence for each of the assumptions which it makes. I have heard perfectly plausible psychodynamic explanations of why research is threatening to patients but, interestingly enough, equally convincing psychodynamic explanations of why it is supportive. Since the evaluation of the efficacy of even the major forms of psychotherapy has been so long in coming, I doubt that anyone has had the means or the inclination to test the comparatively trivial question of the effect of skepticism in the therapist. In the long term study of Whitehorn and Betz(32) on the relationships between personality factors of therapists and their therapeutic results in schizophrenia, although many variables have shown a significant relevance, skepticism or conviction have not been among them. To the hypothetical opinion stated above, I should like to offer a counter one. This would be that, just as the "training for uncertainty" is important in the education of other physicians(33), so this feeling of uncertainty and humility is of value to the psychiatrist; that the average patient is sensitive enough to recognize what the psychiatrist can be expected to know and what he cannot. It is possible that confidence is reinforced when the psychiatrist speaks authoritatively from his vast and special experience with observations of other human beings in similar situations and when he makes recommendations based upon them. When in addition he admits that he, and medical science generally, do not know all of the answers to the causes of the problem, it is even possible that this may strengthen the human bond between them. In any case, if we agree that neither one of these two opposing hypotheses has been proven, we can at least make a reasonable prediction of what the

result would be if we assume one or the other to be correct and behave accordingly. If skepticism were repressed, would we not guarantee that progress will stop and present opinion be perpetuated and even reinforced by the uncritical selection of data from the vast supply available? On the other hand, will not the skeptical attitude, on the basis of all our experience in other scientific disciplines, make for revision and improvement and progress?

Another major problem, often a bar to psychiatric research, is the idiosyncratic nature of human personality and therefore presumably of mental illness. There is no doubt at all that human beings differ remarkably one from another, not only in the field of personality, but also in every anatomical and physiological aspect. It is also true that the personality differences are such that the variance which may be introduced in that sphere or in behavior by individuality is magnitudes greater, because of the tremendous leverage in the behavioral field, than the variance which occurs, let us say, in the action of the heart or in the digestive system. Admitting freely that each individual is a phenomenon unique in the universe, there is still the question whether that individuality depends upon a specific arrangement and weighting of a considerably simple alphabet of common factors, or whether the very alphabet is unique to the individual. All the biological and the behavioral sciences are based upon the assumption of common factors of which we all partake in different degrees and combinations. Psychodynamic theory not only accepts but is based upon the existence of these common factors; indeed, I never cease to be impressed with the small number of variables into which that theory in its classical forms has managed to compress so many aspects of human behavior. If the assumption of the importance of common factors is correct, then psychiatry is not qualitatively different from every other field of biology which, recognizing the uniqueness of the individual, nevertheless attempts to study the common factors and how they are combined to produce that individuality. Statistical techniques have been devised, are available and are being used in every other science which permit

one to tease out the variables involved and to weight them appropriately in the resultant, and psychiatry has begun to take advantage of them.

An unfortunate corollary of the recognized idiosyncratic aspects of personality is the rather alarming tendency today to neglect the older concepts of nosology and the description and classification of mental disorders. Diagnosis is undervalued and mental illness is being regarded less as a "disease" or even a "disorder" and more as "a way of life," or an individual adaptation to a unique life situation. If such were the case, of course, it would follow that what was formerly thought to be a categorical disorder is now unique for and peculiar to the individual patient. It would follow, also, that there is little sense in concerning oneself with "schizophrenia" or "anxiety neurosis." One should really speak of John Jones' Disorder or Mary Smith's Syndrome. Here again I fear that we are dealing with a hypothesis which is being given the clothing of a fact. It is easy to see how appropriate and important it was to emphasize the concept of individuality at the time when Adolf Meyer did so, when Kraepelin's nosological categories were generally assumed without evidence to represent diseases with specific and simple etiologies, pathogeneses, predictable prognoses, and

stipulated treatments. It is no longer necessary to accept either assumption; it is quite possible to recognize that phenomenologically at least there are significant clusters in the expression of mental disorder. It seems rather rash to discard the decades of careful clinical description for an unverified hypothetical postulate. Of course it is possible to exaggerate the diffuseness of these categories by concentrating upon the relative minority of patients who seem not to fit neatly into any of them, but in doing so we forget the many who do and their general consistency and reliability.

In Vera Norris' comprehensive study of mental illness in London (34), there was a recent opportunity to re-examine the reliability of some of these classical diagnostic categories, in a study of a large series of patients who were seen and diagnosed in a brief observation at a receiving hospital and in a much longer stay in a mental institution. It should be pointed out that no effort was made to emphasize the importance of diagnosis or to refine the diagnostic techniques since this study was done after the fact and represents the unpremeditated, unimproved reliability of the diagnostic categories as they are employed in London. Table 1 represents a summary of her results, indicating the percentage of concordance in the diagnosis between the 2 institutions for

TABLE 1

Diagnostic Concordance Between Observation Unit and Mental Hospital
(from V. Norris, *Mental Illness in London*, 1959)

	% concordance	
	Men	Women
Schizophrenia	74	62
Manic Depressive	63	69
Senile psychoses	61	61
Epileptic psychosis	93	88
General paralysis	90	78
Alcoholic psychosis	79	48
Psychoneuroses	62	46
Mental deficiency	75	68
Disorders of character and behavior	44	42
All psychiatric disorders	62	58

each of several diagnostic categories. There is a remarkable consistency here, all the more remarkable since most of these diagnoses are made without the advantage of x-rays, blood tests, or other objective and sometimes pathognomonic criteria. I wonder whether a random sample of medical diagnoses generally would yield a significantly higher reliability. It seems unfortunate to close our eyes to these obvious clusters as a reaction to preconceived and unwarranted notions of their significance with regard to etiology, genetics, prognosis or therapy. Where we have no clear idea of etiology or pathogenesis, treatment should and will continue to be based upon the individual interaction between the patient and his life situation. But to discard those common clusters of symptoms is to throw out information and exaggerate chaos.

It has been said, usually by those outside the field, that psychiatry depends too much upon subjective observations ever to become a science. To this I take strong exception. It is not subjectivity itself which keeps a field from being scientific, but a failure to recognize, minimize, or compensate for subjective error. The human senses are notoriously imprecise, variable and fallible, although this ignores the ear of a Toscanini which could recognize a deviation from the correct frequency of 1 part in a thousand. Used properly, however, all that the unaided senses of those of us not so gifted need introduce into the observation is a larger standard error of measurement. The internist of 150 years ago is reputed to have been able to diagnose diabetes mellitus by tasting urine, and even today some research has been done in which the most sensitive instrument which could be found was the nose of expert tasters(35).

But human observation and subjective evaluation is corruptible, infinitely more so than the needle on a spectrophotometer. It is notoriously influenced by the motivation of the observer, the internal or external rewards which come from making a discovery, and from various social pressures. Mouton and his associates(36) have shown that so simple a task as counting the clicks of a metronome can easily be made to yield false results if such are reported by others. This pressure of subjective bias operates

in two interesting ways. In the first place, it may obviously influence the initial data themselves, certainly when they are subjective but even when they are as objective as the taking of a reading on a calibrated scale. It is a commonplace observation in a laboratory of physics or chemistry that such readings are not entirely independent but are influenced by previous ones, so that the careful physicist makes sure that knowledge of a previous reading is obliterated by a process of randomization in obtaining each new one. Where the observation itself is subjective, however, the problems are greatly increased. The psychopharmacologist has attempted to get around this difficulty by the use of the so-called "double blind technique," in which, if properly used, the chance that the crucial observation will be influenced by knowledge of the hypothesis or of the expected results by either the patient or the observer is minimized. It is relatively easy to do this in drug studies and in other biological observations and all the more lamentable when it is neglected, as it so often is. I have in another context pointed out the deficits in biological research in schizophrenia in this regard (37), but similar or even greater deficits exist in other areas. The double blind design has had practically no application as yet in studies of social and psychodynamic variables, especially at the clinical psychiatric level. The genetic studies in schizophrenia have not taken every precaution to prevent the hypotheses being tested from contaminating the data being recorded, while in the growing field of the possible influence of family factors on the genesis of schizophrenia few of the studies have taken this problem into account.

John Clausen in his excellent review of *The Sociology of Mental Illness* points out some of these influences(38) :

These theories have been derived from studies of schizophrenics and their families after they have accommodated themselves, in one way or another, to the fact of illness. The processes observed in the families of schizophrenics under treatment may be resultants of the families' experiences with the illness rather than factors of etiological significance. In some instances, indeed, it appears that the conditions under which the families are studied may

themselves accentuate the relational tendencies to which attention is being called. The test of these theories requires work with normal families from a variety of backgrounds, in a variety of observational settings.

Even after that is done it will be necessary that the observer who is evaluating the family setting be kept free of bias regarding the presence or absence of a schizophrenic member. Of course to do truly double blind, well controlled research in these fields would be a Herculean task; most of the past and current investigation is still in the stage of pilot studies in which hypotheses are being generated rather than tested. One hopes, however, that before these hypotheses are accepted by the investigators or by psychiatry generally the problems inherent in performing such a study will have been worked out.

Most scientists in every discipline are aware of this common source of error and attempt sooner or later in the development of their study to prevent it by appropriate research design. A more subtle type of subjective bias which is not as generally recognized is the conscious or unconscious selection which is interposed between the taking and reporting of an observation. There is a universal and perfectly human tendency to accept uncritically those observations which support one's preconceived or hoped-for notions, and to examine much more critically and reject for what apparently is good cause the observations which tend to discredit them. Hardly ever are the conditions under which an observation is made completely perfect, in most types of research with which I am familiar. There are always factors such as temperature deviations, changes in atmospheric pressure, in pH, in the reagents, in the subject, or in the observer, in every observation that has ever been made. It is an easy matter, therefore, to find valid and convincing evidence for the rejection of observations that one does not like. This, I suggest, has been a major source of confusion and error in the scientific literature.

This failing is not peculiar to psychiatry or even to biology. We all secretly envy the physicist who deals with such beautifully precise and objective instruments and such

simple and immutable phenomena. Figure 2 is a chart of the measurements of the velocity of light which have been made throughout the world in the past 30 years (39). I have deliberately broken the ordinate in order to exaggerate the errors involved and to make them less humiliating to biological and behavioral scientists. Although the magnitude of errors is perhaps 10,000 times less than the errors with which we deal, their effect upon the measurement and the reasons behind them appear not to be materially different. We note that over the 30 years in which these particular measurements have been made there does not appear to be a random scatter of the results which we would expect through the operation of experimental error. Rather there seems to be a clustering of the results, for which one can offer some hypotheses. The first result is one which was made by Michaelson in 1926 and was somewhat lower than the value accepted until that time, based upon a considerable number of older measurements. Michaelson was in the midst of making a second series of measurements some years later but unfortunately died before they were completed. His associates published the results posthumously; these results are also shown, significantly lower than the previous ones. Now, interestingly enough, the next several measurements by independent workers in other laboratories seem to cluster about that one. After the Second World War radar was used in the development of a novel technique for measuring the velocity of light which seemed to have certain advantages and which gave a value significantly higher than those of the previous series. This observation was followed by a rash of others, some made by the same techniques which had been used previously, but somehow agreeing more with the new value than the older one.

Now even in the measurement of light velocity all the observations are not given equal weight. Rather it is the tradition to reject certain data on the basis of atmospheric or instrumental vicissitudes, although the number of rejected observations is reported. It is my hunch that in this selection process there is an unconscious bias in the direction of conformity with preconceived notions and accepted values. This hunch

finds support in the opinion of an authority like Professor Bearden, who discussed this question in the *American Journal of Physics* (40). After considering and arguing against pure chance and systematic error, he suggests "that the experiments were not really independent but that there was a subconscious psychological factor which tended to make each experimenter look for errors in technique until he could check the then accepted value. It appears that (this assumption) is the most plausible." Mulligan and McDonald have also discussed this point.³

³ "It does seem clear from the history of physics that occasionally the result of a very high precision measurement of a physical constant by someone eminent in the field has intimidated other workers from publishing results in substantial disagreement with this value . . . As early as 1947 Aslakson found that his 'Shoran' distance measurements required a value of c higher by more than 15 km per sec than the then accepted value. He did not

If the importance of these subconscious psychological and social errors is recognized by physicists, should not psychiatrists be even more aware of them and attempt to avoid them, or at least recognize and compensate for them in their thinking and writing?

In other branches of medicine, the autopsy(42), the x-ray and the chemical

report his results at that time, however, because he thought there must be some as yet undetected error in his work or in the accepted value of the index of refraction at the frequency used which would account for the discrepancy. It was only in 1949, when evidence was mounting from other sources in favor of a higher value of c that Aslakson first published his original evaluation, $c=299,792.4$ km per sec. It seems at least possible that other experimenters in the years from 1934 to 1949 may have found higher values of speed by optical methods but refrained from publishing their results because of their disagreement with the determinations of (others) in which such great confidence was placed at that time"(41).

FIGURE 2
Measurement of the Velocity of Light as Reported in
the Physical Literature from 1926 to 1956

laboratory have served as checks to the reinforcing of clinical presumption of underlying processes by selective observational bias. Such relatively objective and dispassionate guidelines are lacking in psychiatry and it is that lack rather than ineptitude or indolence which has kept psychiatry a young science, comparable to medicine a generation ago.

The idiosyncratic aspects of human personality and behavior plus the lack of objective criteria for the evaluation of progress, have undoubtedly inhibited the motivation and de-emphasized the obligation to test the efficacy of various forms of psychotherapy. They have also formed the basis for a devaluation of the few studies which have attempted to do so. Recognizing that the efficacy of a therapeutic procedure is not a valid test of the theory upon which it is based, Frank has pointed out the need for empirical evaluation of the relative efficacies, by the criteria which we have, among different forms of therapy administered by various therapists to a wide variety of patients (43). We are asking too much if we seek and wait for the one study which will answer all of the questions at once. No surgeon can predict the outcome of a particular operation in an individual patient, nor can one be certain in advance of the effectiveness of each use of an antibiotic or ataractic drug. What we do have, on the basis of empirical studies, some of which are well controlled, is a knowledge of the betting odds, on the basis of which it has been possible to improve the surgical techniques which we have, develop and test new drugs, and more sharply define the conditions in which each therapy is most effective. Every therapist, be he surgeon, internist, or psychotherapist accepts a patient for treatment without knowing all of the individual factors which will determine the final outcome, but on the basis of hypotheses that he can help such patients. Those hypotheses can be tested.

Recognition of the problems and imaginative scientific design can, I am sure, find substitutes in psychiatry for the simpler objective criteria which are available to other disciplines. Much has already been accomplished, but it will take continued alertness to the common pitfalls of science and those

peculiar to psychiatry, a wealth of ingenuity and a vast expenditure of time and effort to meet the challenge effectively. It will also require patience and forbearance if we are to avoid the reactive swings which have marked psychiatric thinking in the past. For we must also realize that research and scientific methodology are developing to enrich psychiatry and not to impoverish it of its other qualities. No sophistication of scientific design can take the place of the imaginative and creative spirit, no amount of research output can substitute for a sensitivity to human problems and a willingness to utilize appropriately the knowledge which we have, at every stage of our progress, in service to the individual human being and his community.

THE CHILD WHO REFUSES TO ATTEND SCHOOL¹

T. P. MILLAR, M.D.²

This paper will discuss a syndrome that is appearing with increasing frequency(4) in psychiatric clinics for children. The principle presenting symptom is the reluctance and ultimate refusal of the child to attend school.

THE SYNDROME

The failure to attend school in such cases can be differentiated from truancy in 3 particulars: 1. Unlike the truant, the school-refusing child goes home and stays home or nearby. He does not go fishing or to the ballgame. 2. The absence of the truant tends to be intermittent and for short intervals of a day or so, whereas, the school-refusing child absents himself for days, weeks, or even months at a time. 3. The truant is absent without the knowledge of his parents. The essence of school-refusal is that while the parents are painfully aware of the absence of the child they are powerless to enforce his attendance.

In the beginning, the child may not directly refuse to attend school. More frequently somatic complaints such as abdominal pain or nausea, headaches or dizzy spells raise a question in the parents' minds about the advisability of sending the child to school. These physical complaints tend to recede quickly if the child is permitted to remain home but they are frequently aggravated if the child is taken to school. While these symptoms may have somatic roots in that they are sometimes vegetative concomitants of anxiety feelings, it is doubtful however if they should be accorded the dynamic status of conversion reaction.

If the parent attempts to force the child to attend school, the "refusal" aspect of the nonattendance becomes more evident. The child will often become anxious, make protestations of pain and fear. If the parent is insistent he may go on to angry accusations, even blows. Once the parent capitulates and allows the child to remain home,

relative peace is rapidly restored.

The core symptom, then, is a failure to attend school, with the knowledge of the parent but beyond his control.

DIAGNOSTIC CATEGORIES

In the literature this symptom has sometimes been described as a single entity and accorded the name "school phobia." Recent articles(3, 12, 16) show that the symptom appears in a variety of psychopathological configurations. There are 3 main categories so described. While the focus of this paper will be upon the acute or neurotic syndrome, for clarity, the other categories will be described briefly.

Acute School Refusal: The sudden appearance of reluctance and refusal to attend school constitutes the principle symptom. These children are usually pre-pubertal and most frequently from grades 4 down to, and including, kindergarten. This syndrome will be described in more detail later.

Characterological School Refusal: While reluctance and ultimate refusal is a prominent symptom in characterological cases, it does not occupy as central a position in the psychopathology. Social difficulties with peers, affective disturbances and acting out behavior of a mild or predelinquent kind are not infrequently part of the picture. Indeed, in the author's experience, an active peptic ulcer complicated one such case in a 14-year-old boy. School refusal may be accorded undue emphasis in the symptom complex because it is most frequently this difficulty that brings the child to the attention of agencies, psychiatrist, or authorities. This category of school refusal is more common in children of early adolescent years, and most authors feel that it represents a more severe personality disturbance in the child than does acute school refusal; parental psychopathology appears to be of greater magnitude in such cases. Here one is not describing acute school refusal cases that have been permitted to go on to chronic nonattendance. The deterior-

¹ Read at the N. Pacific Society of Neurol. and Psychiat. meeting, Apr. 8, 1961.

² 1214 Boylston Ave., Seattle, Wash.

ration of such children shows a rather different picture than that of the characterological school refusing child.

School Refusal as Incipient Psychosis: The least frequently seen category is that which heralds the onset of a psychotic illness in an adolescent child. In the author's experience, the refusal to attend school in these cases, has been explicable on the basis of the first appearance of psychotic manifestations in the classroom. Experiencing frightening hallucinations or delusions in that setting, the child avoids attending.

THE ACUTE SCHOOL REFUSAL SYNDROME

It is proposed to describe more fully the acute pattern of school refusal as a basis for discussion of the dynamics, treatment and prognosis of this particular condition. In addition to refusal to attend school, such children frequently show disturbances of affect, behavior and self concept. Affective disturbances are revealed in the history as well as in the presenting picture. Parents report that such children have often had many fears during early development, *i.e.*, fear of dogs, the dark, thunder, lightning, *etc.* Indeed some authors have felt⁽⁴⁾ that a proneness to anxious affect exists in these children.

Much has been made of the child's fear of school. It is the author's experience that there is question as to whether these children are actually afraid of school, *per se*. It may be that principals and teachers, apprehensive over the role of the school in initiating the child's difficulties may suggest to the child that he might be fearful of one or another aspect of his school experience; parents, seeking to extenuate the child's failure to measure up to social expectations may also suggest that he is afraid of school; therapists, seeking to confirm dynamic formulations may induce such children to produce the expected confession of fear of school. While children may report a fear of school and even focus upon a particular teacher, child or classroom, such frequently seems to be more of an afterthought, than a true phobic anxiety.

A more clearly observed anxiety centers around the child's need to be near his mother constantly. When these children are not attending school their concern over

separation from mother is so great that they often need to keep her within sight, if not touch. One mother reported her child followed her about the house constantly, even sitting with his back to the bathroom door when she used that facility.

The most constant anxiety fantasy reported by these children is of accident or injury occurring to their mothers while they are absent. It may be that the anxiety observed in the classroom is related to pervasive obsessional thoughts of injury or accident having occurred to the parent while the child is at school. Some children report such obsessional thoughts. The desire to remain at home may be motivated by their need to be assured of the well being of their parent. Their personality structure is such that they may also feel that their presence with the parent will confer a magical protectiveness.

One of the most striking observations is of the child's need and ability to manipulate and control his parent through mobilizing and exploiting her guilt feelings, self doubt and subservience. Tears and tantrums would seem to be more in the service of maintaining such control than representative of depressive affect or hypomanic behavior⁽¹⁾.

In some cases the extent to which the child controls the family is remarkable. Not only does the child decide when and whether he will attend school, but meal and bedtime as well as many other aspects of family living may be subject to his decision or, at least, veto. The social and personal life of his parents and siblings may be subject to his tyrannical control. These children are particularly sensitive to the doubts and uncertainties of their mother and exploit these feelings to retain their control. When parental compliance is not forthcoming, tears, tantrums and, in some cases, threats to kill themselves and the parent ensue.³ These children are filled with hostility. While this affect sometimes erupts in the threats described, it is more generally passively expressed. Manipulation and control of the family gains its impetus from this

³ Tyrannical over-control of the family by the child is sometimes seen in children who have no difficulty in attending school regularly. The reason for this is not clear.

hostility. The anxiety over accident or injury to the parent is probably a conversion of such feelings.

It should be mentioned that most of these children are bright, frequently good students, sometimes careful and almost obsessional workers. Outside of their homes, they are reported to be mannerly, polite, sometimes excessively conforming. They are alert to the feelings of others. They are extremely perceptive of the clues that enable them to detect the concerns and attitudes of others. While they tend to use this knowledge to further their manipulative ends, their possession of this skill is probably related to the protracted closeness of their early relationship with mother.

Almost all authors agree that a highly specific type of pathological relationship between the mother and the child is usually present. On rare occasions, it is the father who is involved in this particular relationship distortion. The mother is anxiously overinvolved with her child. She tends to overprotect and infantilize him, to have little recognition of his growing capacity for living. Her anxiety as to whether her child can live up to life's expectancies is communicated to the child. She is unable to offer him the limits and expectations that will lead to experiences of mastery and so develop in him a sense of competence and worth. His continued dependence, indeed regression, is thus encouraged.

The mother soon develops a sense of incompetence as a parent which frequently aggravates a basically impaired sense of her own worth. Anxious and hostile feelings develop and a deep ambivalence towards the child is common. While the mother's hostility may erupt on occasion into overt rejection and expressed hatred, it will soon be buried again in guilty overprotectiveness.

Authors disagree as to the reason these mothers become overinvolved with their children. Some see them as immature even infantile persons who have experienced serious difficulty in achieving a sense of independence and autonomy in the course of their own psychological maturation. Others point to the unrewarding quality of the marital life of these women. Their husbands certainly tend to absent themselves

from the situation, to be weakly incapable and to relate themselves superficially to their wives and children. It is postulated that the mother's desire to escape from this unrewarding life situation represents the abandonment of her child and so produces a reaction of guilty indulgence.

It seems likely that in certain cases the above factors are important, however, it may be that the overinvolvement of a mother and her child does not always reflect deeply rooted psychopathology in the mother. Many young mothers today are in the position where they must rear their children with little or no support from experienced relatives. This may well render them subject to increased stress over dealing with their child's growing needs. The popularization of negative psychiatric clichés may have contributed significantly to parental inhibition over controlling their child directly. Fearful of traumatizing her child and deprived of experienced advice it is possible that mother may slip into indulgent management. Where such factors are operant the capacity of the parent to respond to psychiatric assistance is understandably greater than in those cases where severe conflict over unresolved dependency needs have produced mother's overidentification with the child.

DYNAMICS OF THE SYNDROME

Several authors have suggested that the term "school phobia" is misleading (4, 5, 12). However, this formulation continues to appear in the literature. It is suggested that anxiety over separation from the mother is displaced onto the school and thus delimited, becoming a fear and phobic avoidance of school. Since these children do not always express a marked fear of school, it is questionable that such a displacement has taken place. Further, their separation anxiety continues unabated. The economic gain to the psyche of a phobia is that by delimiting the anxiety to a specific situation which can then be avoided, the individual gains a greater freedom of function. These children however continue to be bound tightly to their mothers and it seems doubtful that phobic delimitation of anxiety has really occurred. The dynamics of phobia

seem to be questionably applicable to this syndrome.

The use of the term "school phobia" has been dignified by time and were it not for certain psychological consequences of its use, it would be carping to quarrel with such usage. It seems probable that the hesitance of some therapists to insist upon early return of the child is based upon an understanding of the syndrome as a phobia. Feeling the child's nonattendance to be prompted by intense phobic anxiety, such therapists are fearful of precipitating panic attacks by insisting upon return. Similarly the attention of school persons tends to be focused upon the anxiety of the child. This leads them to look for fault in their teachers or program and to protect the child by concessions ranging from limited classroom expectation to home tutoring. In the latter case, the child is denied the opportunity to recover and in the former he is robbed of desperately needed experiences of mastery. Finally, the term phobia focuses upon the anxiety of the child and neglects that most striking aspect of this syndrome, the manipulative and controlling quality of the child's relatedness to his parents. The term "refusal" would seem to be more appropriately descriptive of the situation of the child's nonattendance.

The principle conflict for these children centers about their struggle to achieve "a sense of autonomy, to delimit their own egos, to find their own identity and sense of worth. To this end the child behaves as a tyrant, he operates from a self concept pervaded by infantile omnipotent fantasies. He rules his parent, who sustains these fantasies through protective indulgence. Her mounting resentment eventually erupts into expressions of anger or rejection. In turn the child reacts with hostility which, with magical power born of omnipotence has life threatening dimensions towards his parents. Acute anxiety over separation is precipitated. The child reacts with ingratiating conformity and tearful clinging and the parent is ready to make it up to the child for her recent explosion of hatred. Mutually supportive fusion results and further regression is encouraged. The child reasserts his tyrannical rule over the home and refuses to attend school.

It would seem that the stage is set for this type of relationship by a failure of the child to have his needs met in early stages of his growth. As the infant's growing capacity for self care emerges, his life experiences offer him opportunities to exercise his new capacities. He learns to feed himself, to dress himself, to tie his own shoe laces, to wait a little for his satisfactions. Some children seem to reach actively for such experiences of mastery and growth. Some babies reject their bottles. Some children will not allow their mothers to button their clothes. For some other children however, each new responsibility is greeted as though it were an unwelcome irritation. The parents of such children must be patient and determined if the child is to achieve this step in his growth.

It may be that such differences in children are a reflection of constitutionally determined approaches to experience; it may be that such differences are solely the result of the nature and quality of parental management offered the child. It may be that both factors are operant with varying significance in individual children.

In any case, experiences of mastery enable the child to develop a sense of himself as an autonomous individual. With each new expectancy encountered and mastered, the child achieves a growing sense of his personal worth. Gradually, he exchanges the omnipotent fantasies so essential to his security as an infant for a view of himself as a separate individual, albeit less than totally self determining, yet with capacity and worth.

Denied limits and expectancies to grow against children are infantilized. Their omnipotent fantasies persist; their personal autonomy is stunted in its development. When life requires them to leave the protection of home to attend school, they are forced to view themselves comparatively for the first time. Their fragile sense of worth may not sustain the comparison, and a tendency to regress to more infantile modes of behavior results.

TREATMENT

To be effective treatment must be instituted promptly and must include early return to regular school attendance. Follow

up studies have shown a clear relationship between the effectiveness of treatment and the promptness of its initiation(12, 16). These children cannot be allowed to languish on waiting lists; their condition should be regarded as an emergency.

The first phases of treatment are concerned with the child's early return to school. Some authors express concern over action preceding insight and are concerned that panic states not be precipitated. Most writers however feel that prompt and vigorous action to return the child to school is indicated. In order to achieve this goal it is necessary to deal directly with the concerns of the parents, the child and the involved school persons.

The parents should be informed that the child's problem is not school and that his interests are not served by his nonattendance. The difficulty they experience in knowing how to deal with the child's behavior is acknowledged and accepted as a product of their desire to help the child. It is pointed out, however, that their present measures are currently ineffective. A date a few days hence is set for the child's return. It is sometimes helpful to involve the father in the mechanics of conveying the child to school. The difficulties of the first few days can be dealt with more effectively if the parents are told that they may call the therapist in the mornings if difficulties develop. Plans for ongoing treatment involving mother and child are made. The parents' questions are answered and their anxieties handled with firm support.

The child is informed that the therapist realizes that he has a worrisome problem but also that this problem is not at school. It is pointed out to him that nonattendance has not solved his problem nor has it made him happy. Return to school is defined as his obligation and attendance as not a matter of his particular choice. He is informed of the plan to begin attending on the arranged date and also that he will be seeing the doctor regularly. He is told that the purpose of seeing the doctor is to discuss any concerns he might have about his return or other problems. From the childrens' demeanor it is frequently apparent that they are suspending judgment as to whether or

not this is the way events will actually proceed.

The principal is contacted and informed of the plan to return the child. His concern that the school may have done something to contribute to the child's fears is dealt with by a brief explanation of the state of affairs. The principal is discouraged from making any special concessions for the child's educational program and told that such would not be in the child's interests. He is encouraged to use the nurse's office rather than permit the child to go home should physical complaints develop.

Using such methods, it is the author's experience that acute school refusing children are usually attending regularly and without difficulty within 2 weeks. In a few cases, the child returns immediately without protest on the date assigned. It is as though the child recognizes the new determination of his parents and elects to return without protest. In the usual case however, the child struggles against returning with somatic complaints, tears and tantrums. Not infrequently the parents telephone for reassurance and instructions and the therapist can help them to convey the child to school by direct advice. For example, one girl refused to put on her skirt; her father was instructed to place the girl and her skirt in the back seat of the car and was assured that she would put it on when she arrived at school. She did. Many children leave school during recess or lunch period to go home. They should be returned the same day. Usually, progressively diminishing difficulties persist through the first 3 or 4 days of the first week and sometimes 1 or 2 days of the second week. Panic reactions do not occur nor do other phobias develop.

The experience of attending regularly represents a shift in the adjustment of the child. For example, one such child was returned with difficulties lasting for 2 weeks. He had been in school slightly over a week when he contracted a communicable disease and was excluded. It was of course feared that it would be necessary to repeat the full process, however, the child returned willingly after he was well.

Continuing treatment involves parent and child. With the mother a directly supportive

relationship is provided. She is given the opportunity to ventilate some of her feelings for her child, her marriage and her self doubts as a mother. She is encouraged to discuss the details of the child's home management. She is supported in setting limits around such matters as bed and mealtime if these are out of her control. She is encouraged to offer the child increasing expectations in specific areas. It is necessary to enquire further concerning such expectations for not infrequently the child may have bargained so effectively as to nullify the mother's control.

If the mother receives clearly enunciated and firmly reinforced recommendations from the therapist, she tends to begin dealing with the child with similar clarity and firmness. Mothers will frequently come to recognize that they have been oversensitive to the emotional reactions of the child, that in actuality the depth of feeling imputed to the child was somewhat greater than he was truly experiencing. Further they come to recognize that the child can cope with some distress, disappointment, sadness, or fear without being overwhelmed.

As the child and mother achieve some initial separation, their relatedness to one another tends to improve and generally continues to do so somewhat independent of events in therapy. The child is initially guarded and tries to control the therapist as he has done his parent. When he recognizes that he is unable to do this and that the therapist is behind the new self respect of his parents, he may attempt to undermine treatment by mobilizing the parents anxiety concerning it. Ultimately however these children give up their manipulative behavior and develop more meaningful relationships to the therapist.

Some authors have expressed concern that direct supportive involvement with the mother would tend to perpetuate her dependency upon the therapist. This does not seem to be the case. Rather, the setting of limits helps her to achieve a greater personal autonomy. If the therapist is alert to her increasing capacity to take over decision making and allows her to do so, her independent functioning is encouraged.

Termination of treatment tends to occur as a result of pressures from the parent.

When their relationship with the child has improved with the disappearance of tears, tantrums and tyranny and the child is attending school regularly, they see less need for treatment.

PROGNOSIS

The prognosis is related to the nature of the psychopathology in a given case and the real meaning of the therapeutic interference that has taken place.

Follow up studies in acute cases are encouraging in that the same or other adjustment difficulties are rarely found (12, 16). Symptom displacement does not seem to occur. This would tend to lend credence to the view that acute school refusal may represent more of a situational reaction than a structured neurotic illness. The relationship difficulties of the parent and child might more profitably be viewed then as an impasse or blind alley in the child's psychological maturation. Treatment restores the mother and child to a more normal parent-child interaction and normal emotional growth is once again possible for the child.

As long as the child remains out of school normal psychological maturation is impossible. He can only stand still or regress. In those children who have been out of school, for a year or more, severe regression tends to crystallize in an infantile personality structure, social alienation and even paranoid traits. For such children separation from their home and a period of residential treatment is often necessary. The price of failure to treat these children promptly is very high.

SUMMARY

School refusal would seem to be a symptom complex appearing in more than one psychological configuration. In its acute form, it is felt to arise out of difficulties that the child has experienced in achieving a sense of autonomy. This has been due primarily to fluctuant limit setting by over involved parents. Direct management of the situation to control the symptom is essential to restore the child to normal growth patterns. Since symptom displacement and recurrence are not common it is suggested that the symptom in its acute form is more

situational in character than indicative of a structured neurotic illness.

INQUIRY INTO THE USE OF PSYCHOTHERAPY FOR HOSPITALIZED SCHIZOPHRENICS¹

PAUL E. FELDMAN, M.D.²

There is ample reference in the literature to the treatment of schizophrenic patients with the psychotherapeutic method, and, in clinical presentations and discussions, psychotherapy is frequently mentioned as indicated or highly desirable. Despite this, there is difficulty in ascertaining the status of this method in the treatment of schizophrenic patients, both as to the frequency of its use and the current consensus towards its effectiveness. Occasional authors have reported their individual or group experiences but statistics have not become available which would reflect the picture on a nationwide basis.

This inquiry which is herein reported pertains to a beginning attempt to define the status of the use of psychotherapy with schizophrenic patients by collecting data regarding one segment of the problem. In addition, it was presumed that the data might provide correlation between the extent of its use and other factors such as the number of professional personnel, the number of staff personnel with special or particular skills and their attitudes towards other therapeutic tools. To this end a plan was devised to study, from reports obtained from a representative list of hospitals, the use of psychotherapy with hospitalized schizophrenics. These hospitals were derived from listings provided by The Joint Information Service of the APA, The National Institute of Mental Health, The APA Mental Hospital Service and The Council of State Governments. All private, general hospitals in the United States which admitted 100 or more neuro-psychiatric patients per year were included.

Hopefully, the judgements of effectiveness to be collected from the various hospitals would be based upon results obtained by their therapists who had had specific

experience in the use of psychotherapy with hospitalized schizophrenic patients and in a setting where judgements regarding use of other methods would also be available. It could be anticipated that these judgements would not always be derived from well-organized evaluation studies of psychotherapy since few of these exist, but rather would include judgements based upon general impressions from experiences within their own hospitals.

A questionnaire was designed to secure the following specific information³: 1. Data concerning hospital census, number of schizophrenic patients, staffing patterns and the extent to which various psychotherapeutic methods were used; 2. An expression of opinion as to the effectiveness of psychotherapy based upon the experience of each hospital (in detailed percentages and figures when available; when not, in general terms); 3. A definition by each source of the criteria used for determining changes occurring with psychotherapy; 4. An expression of opinion as to the effectiveness of psychotherapy compared with other treatment methods; 5. The extent of inservice training in the various psychiatric disciplines; 6. Proportion of staff with special training; e.g., personal analysis, psychotherapy under supervision, etc.

DESCRIPTION OF SAMPLE

Eight hundred and twenty-four questionnaires (and a follow-up inquiry to some) were mailed to State, Veterans Administration, Private Psychiatric and Private General Hospitals during the Summer-Fall 1959. Ninety-four percent of the V. A. Hospitals and 73% of the State Hospitals responded. For the final sample, it was necessary to delete 270 hospitals who responded with insufficient data; many of the private and city hospitals that responded were unable to provide the information requested but since these hospitals account for but 4% of the total hospitalized schizophrenic census, the final sample (Table 1) appears to be

³ For the period of July 1, 1957 to July 1, 1958.

County	24	7	29
TOTAL	554	309	56

tients. All but three states contributed data to the survey (Table 2). This nationwide response minimizes the possibility of regional bias influencing the final sample judgements.

From the pooled data, certain trends could be charted: 1. The proportion of hospitalized schizophrenics being treated with some form of psychotherapy; 2. Attitudes regarding effectiveness of this therapeutic tool; 3. Judgements regarding its

effectiveness as compared with other types of therapy; 4. Available psychiatric personnel (with and without special training) to administer psychotherapy; 5. Correlation between the extent of the use of psychotherapy and the extent of training of the staff; 6. The availability of psychotherapists other than physicians (ancillary personnel).

ESTIMATION OF EFFICACY

Most of the respondents made a definite commitment as to their opinion of the efficacy of psychotherapy in treating schizophrenics. In those instances where specific figures were provided, if half or more of the patients treated were said to be benefited, the respondent was considered to have a favorable opinion of its efficacy, and *vice versa*.

A wide variety of opinions were expressed. Within this range, 43% had a favorable opinion of psychotherapy in the treatment of schizophrenics; the remaining 57% decline making a value judgement or considered its efficacy unfavorable. Among those who had a favorable opinion, many made

*** Training in Psychotherapy.

the reservation that their opinion was favorable only if the patient received some form of somatic therapy first or concurrently. Some respondents expressed favorable opinion of the usefulness of psychotherapy in the earlier phase of schizophrenic decompensation and considered it without value in the chronic, later phases. Others felt that psychotherapy had a contribution to make but was inadequate by itself. Others utilized psychotherapy in conjunction with other methods and were reluctant to make a value judgement of its singular use.

The majority of the V. A. and State Hospitals indicated that they did not view psychotherapeutic treatment of schizophrenia as effective. There was no reference to a lack of personnel to explain the meager degree to which it was used. The private, general hospitals responded more dogmatically, specifying that psychotherapy was not a satisfactory substitute for somatic therapy. The private, psychiatric hospitals (where 100% of the schizophrenics were reported as receiving some form of psycho-

therapy) had as many reservations about its efficacy for hospitalized schizophrenic patients as did the other hospitals.

CRITERIA FOR IMPROVEMENT

The majority of the reporting hospitals used essentially the same criteria for determining improvement, the most common being : 1. Separation of patient from the hospital ; 2. Evidence of increasing socialization ; 3. Psychiatric evaluation ; 4. Psychological examinations.

COMPARISON OF PSYCHOTHERAPY WITH OTHER TYPES OF THERAPY

With minor disagreement, the opinions or judgements expressed view psychotherapy as being just as, or more effective than, the common or more easily available therapies such as vocational, recreational, occupational or milieu. Opinion seems to be evenly divided as to its efficacy compared with electroconvulsive and insulin coma therapy. Only in the case of psychopharmacotherapy is there a clear cut preference, this latter

being considered a superior form of treatment (Table 4). The V. A. Hospitals differ

of patients receiving psychotherapy and the extent to which inservice training is pro-

TABLE 4
Psychotherapy Rated Against Other Modalities

Psychotherapy Just as or More Effective Than :

MODALITY	STATE	TYPE OF FACILITY			CONSENSUS
		V. A.	PRIV. PSYCH.	PRIV. GEN.	
Carbon Dioxide Therapy	89%	90%	100%	66%	85%
Vocational Therapy	84%	79%	100%	79%	84%

from the consensus in that they view psychotherapy as superior to ECT and insulin coma therapy. The private psychiatric hospitals view psychotherapy as being equally effective as psychopharmacotherapy and the private general hospitals show a preference for ECT and insulin coma therapy.

INSERVICE TRAINING

Inservice training (other than pastoral training and psychiatric residency) is encountered most frequently in the V. A. Hospital system. The two exceptions noted occur most frequently in the state hospital systems. There is considerably less inservice training in the private psychiatric and general hospitals.

First examination of the data suggests an inverse relationship between the percentage

moted. As seen in Table 5, however, the difference in staffing patterns and the greater caseloads of the State and V. A. Hospitals (as compared to the private facilities) seem to account for this discrepancy. Among trained personnel, the reported case loads of 92-169 schizophrenic patients per therapist, in addition to the other commitments, are far from conducive to the development of psychotherapy programs.

PERSONNEL RESOURCES

Staffing patterns appear to be related to the use (and also the acceptance of) psychotherapy. In those hospitals (private psychiatric and general) in which psychotherapy is used extensively, small case loads are noted. Conversely, in the V. A. and State Hospitals, there appear to be fewer trained

personnel to carry out psychotherapy programs.

SUMMARY AND CONCLUSIONS

Questionnaires were sent to hospital administrators who referred them to their clinical directors, chiefs of service or directors of professional services. The data thus obtained represent the judgements of psychiatrists with varying degrees of training, a variety of philosophies of treatment and a variety of types of hospital facilities.

The data which have been collected constitute current judgement values. Those respondents who could not draw on specific experiences within their own hospitals did not offer judgement values. The opinions expressed—though sometimes based on impressions from experience rather than on organized evaluative studies—are essentially from hospitals where therapists have experience with both psychotherapy with schizophrenics and the somatic therapies.

The data in this report are based upon a survey of more than 150,000 hospitalized schizophrenics in more than 300 psychiatric facilities of various types. The bulk of the schizophrenic patients in this sample (79%) are hospitalized in the various state institutions; the V. A. facilities account for an additional 17% and the remaining 4% are hospitalized in the private hospitals.

The percentage of the schizophrenic population receiving psychotherapy is lowest in the state hospitals and highest in the private hospitals. The extent to which psychotherapy is employed in a given type of facility does not necessarily indicate the attitude of the personnel of that facility regarding its efficacy. Closely correlated with the extent to which psychotherapy is employed is the size of the psychiatrist's case load. The number of ancillary personnel trained in the use of psychotherapy appears to be negligible.

Hypnotherapy and psychoanalytic therapy were found to be used in less than 1% of hospitalized schizophrenic patients. Of the few who receive these therapies, most of them are being treated in the private facilities.

The judgements obtained view psychotherapy as more or just as effective as the vocational, recreational, occupational and milieu therapies, and on a par with ECT and insulin coma therapy. Pharmacotherapy is viewed as the superior treatment. The majority of respondents favor (in emphatic terms) somatic therapy in the treatment of schizophrenia. The data suggests that psychotherapy is infrequently employed as the primary or sole treatment. As an adjunct to other methods it enjoys wider (though limited) popularity and acceptance.

This survey indicates that psychotherapy, in the treatment of hospitalized schizophrenics, is not used as extensively as other forms of therapy. The consensus suggests that it has little value as the sole method of treatment and that its merits may be only as an adjunct to the somatic therapies. Psychopharmacotherapy appears to be the treatment of choice for this group of patients, and this is reflected in the relatively small proportion of hospitalized schizophrenics receiving psychotherapy at any phase of their illness. An inference from the data may well be that the type of schizophrenic process found in the chronically hospitalized patients is not generally responsive in a major way to psychotherapy. Additional factors obviously are large caseloads and limited trained personnel to carry out psychotherapy. The small or private hospitals report a much more frequent use of psychotherapy.

The findings of this preliminary survey describe in a general way a nationwide picture of the use of psychotherapy in the treatment of hospitalized schizophrenics and the attitudes, whatever their derivatives, towards its usefulness. Studies of a more definitive nature will doubtlessly become increasingly available. Even more necessary will be studies of the types of patients treated with psychotherapy, an exploration of the nature of the psychotherapy employed, and a more refined analysis of the derivatives of attitudes regarding the efficacy of psychotherapy.

GROUP METHODS IN HOSPITAL ORGANIZATION AND PATIENT TREATMENT AS APPLIED IN THE PSYCHIATRIC TREATMENT OF ALCOHOLISM ¹

H. WALTON, M.D. (CAPE TOWN), D.P.M. (LOND.) ²

This paper describes briefly the organization and the therapeutic plan in a community hospital for treatment of alcoholism, under direction from the psychiatric department of a teaching hospital.

Increasingly, as the concept of alcoholism as an illness becomes widely accepted (1), psychiatrists are implicated in measures to combat the disorder. When in a community a psychiatrist undertakes to organize treatment facilities, some of his recommendations will be unsupported by validated clinical knowledge. What predictably effective techniques are there for treating alcoholic patients? And if there are such techniques, what assurance can be offered that they will prove workable under the particular geographical and socio-cultural conditions in question, that patients will present themselves for treatment, and professional personnel be available to carry it out?

Alcoholism is not a disease entity. Precise clinical or aetiological definition of alcoholism is lacking; various social, psychological or physiological factors may be operative. In psychiatric respects, alcoholic patients fall into a number of nosological categories (personality disorder, psychoneurosis or psychosis) and, in the opinion of some authorities (2, 3), certain socially-habituated alcoholics may have relatively normal personality structure. Reports from different centers undertaking treatment of alcoholism are not comparable because different types of patient may be involved; furthermore, uniform follow-up procedures are seldom adopted.

A PILOT CLINIC TO ASSAY COMMUNITY REQUIREMENTS

To test the demand for treatment, and to

detect what type of alcoholic patient would present in Cape Town, an announcement of treatment facilities was posted outside a house on a main road, and those interested were informed of a weekly evening clinic.

This clinic was conducted as an open meeting, on modified group therapy principles; opportunity for individual contact with alcoholic patients occurred after each meeting, when the psychiatrist offered outpatient treatment through the psychiatric services of the general teaching hospital. The weekly meetings were attended by drinking alcoholics seeking treatment, by members of local branches of Alcoholics Anonymous helpful in starting the clinic and known to the psychiatrists by wives of alcoholics not willing to come for treatment, and by local committee members of the National Council on Alcoholism.

Numerous alcoholic patients attended the clinic only once, and few of those accepting treatment at the psychiatric outpatient department appeared to improve substantially. However, this outpatient open meeting (retained when the hospital was subsequently opened), in addition to providing supportive psychotherapy to sober alcoholics, demonstrated that without doubt, in Cape Town also, alcoholic patients would come for psychiatric treatment, but that special facilities had to be established. The Administrator of the Hospitals Department of the Cape Province undertook to equip and run a hospital for alcoholism, clinical direction and staffing for which would come from the department of neurology and psychiatry, Groote Schuur Hospital. The Park Road Hospital, a unit of the University of Cape Town Teaching Hospitals' Group, opened March 20, 1959, with accommodation for 30 inpatients in the pleasantly-furnished house with large grounds in a residential suburb.

PRINCIPLES IN TREATMENT

Clinical attitudes tentatively adopted

¹ Read at a seminar on Alcoholism at the New York State Psychiatric Institute, on Nov. 21, 1960.

² Senior Lecturer in Psychiatry, University of Cape Town. Currently Visiting Research Fellow, Department of Psychiatry, College of Physicians and Surgeons, Columbia University, New York.

when the hospital opened have been applied for almost two years.

1. *Group treatment is more effective than individual.* Conventional doctor-patient psychotherapy has been relatively ineffective with alcoholic patients(4) and cannot form the basis of a community treatment approach. The patient (as is apparent from his communications in therapeutic groups) when already involved in psychiatric treatment continues to view the doctor as alien and removed, not capable of understanding "the alcoholic." It is a historical fact that it was a lay organization which counteracted prevailing psychiatric pessimism about alcoholism. Medical failure and misunderstanding was on two scores: (a) The psychotherapist does not have techniques for enforcing a demand that the patient stop drinking; such authoritative restrictions are contrary to the usual method of psychotherapy. The patient in individual psychotherapy tends to respond to stresses in his relations with the psychotherapist by drinking(4). In group psychotherapy, on the other hand, the patient's peers can enforce the requirement for abstinence, by means of group consensus. (b) The physician, failing to view alcoholism as a chronic and relapsing disorder, tended to "reject" the alcoholic who resumed drinking. In this way many patients who may respond to renewed treatment acquire hostile avoidance of doctors. Of the patients treated during the first year in our hospital, 15.6% required re-admission. It is unfortunate that, while the technical nature of individual psychotherapy is widely grasped, the term group psychotherapy gets applied(5) to some attenuated approaches by practitioners not professionally trained (orientation lectures, movies followed by discussion) which, as Agrin(6) has indicated, are more appropriately termed group nontherapy.

2. *Unless socialized, a temporarily abstinent patient will resume drinking.* The alcoholic patient from his teens has had pathological interactions with people in his environment, eased subjectively, but in reality complicated, by habitual use of alcohol. The drinking pattern of a seriously addicted alcoholic is rarely changed unless he gets himself involved in different (non-critical) personal relationships. He some-

times calls for much social casework in his recoupment from the past decades of occupational and interpersonal failure. A wide range of resources available in the community may need to be mobilized if the abstinent alcoholic is to resume normative social participation. Thus the alcoholic rarely can be treated successfully outside his own community. Applications for admission to Park Road Hospital from patients in distant towns have been accepted seldom. To meet these demands, local clinics are being set up in towns, to be conducted by general practitioners who can obtain training at Park Road Hospital, being subsidized financially during training. Patients on return from brief hospitalization in Park Road Hospital will be supervised in their rehabilitation in the community from such local clinics. The efficacy of such geographical splitting of treatment is being observed in the local clinic started in Port Elizabeth, and if successful will be extended to other towns.

3. *The alcoholic must be personally motivated for treatment.* This well known requirement implies that the psychiatrist must improve his techniques for impelling discouraged patients towards detecting their own latent capacities. In our experience, numerous patients acquire added encouragement and resolution upon finding themselves members of a community of like sufferers. Frequently patients about whom a doubtful prognosis was held when admitted demonstrated that the hospital circumstances can mobilize treatment participation. Self-esteem was immediately increased on admission by the pleasant appearance of rooms and grounds, the acceptance by fellow patients, and the technical approaches of the treatment staff.

4. *Hospitalization permits the initiation of treatment.* My clinical impression is that inpatient treatment holds a proportion of those alcohol addicts known as single attenders in all outpatient facilities. The preliminary nature of the inpatient treatment is emphasized as soon as the patient is admitted; the significant treatment is that which the patient will obtain when, as an outpatient, he is establishing himself in the community. Failure to provide intensive outpatient treatment facilities(6), and to stress

rehabilitation as the significant aspect of the therapeutic approach to alcoholism, is a major failure in a treatment program.

5. *Both physical disability and emotional disturbance require treatment.* Medical treatment offers two advantages over a lay approach: (a) In hospital the patient can be treated with drugs during the withdrawal phase, so that interruption of alcohol intake is more tolerable. In addition, physical disorders detected by detailed examination can be treated. (b) Psychothera-

peutic procedures applied in hospital enable the patient to communicate stressful mental preoccupations which, once externalized, undergo reduction of tension-inducing tendency. In the morning group meetings the patient relates distressing past experiences or troubling private resentments, and then frequently ceases to be agitated by them. Matters the patient considers too confidential for group disclosure he may hint at during the full psychiatric examination on admission. During his inpatient stay he also has individual interviews with the consultant psychiatrist to whom he is assigned. The resident psychiatrist is available each day should any patient wish to see him, and any member of the nursing staff reports to him if she observes events she considers significant.

THE STAFF

Careful coordination is effected between the organizational administration (the sphere of a physician-superintendent from the parent teaching hospital) and the clinical administration of the hospital. Through informal encounters and frequent meetings the hierarchical ranking of the staff with

rigid vertical lines of command is counteracted. A basic task the staff sets itself is to facilitate a free flow of communication in the hospital and obviate its collection in pockets. Conflicts between staff members are viewed as obstacles to the team-integration without which patient needs are not adequately met(8). All staff members know at least the outline of the therapy plan for particular patients, so that ambiguity can be avoided. (On one occasion a porter, apparently considered too peripheral to be drawn into the informed circle, was overheard by a startled nurse communicating to a knot of patients his own treatment admonition: "And always remember, boys, only one drink!"). Free communication of hospital information is fostered by a weekly staff meeting of senior nurses, occupational therapist, social worker and psychiatrists, where individual patients are discussed and inter-staff relationships are given attention; policy decisions are made in as clear terms as possible.

The Medical Staff: The psychiatrists(7) meet in a closed meeting fortnightly (the psychiatric social worker also attending). Details are reported by each psychiatrist of the progress of the closed outpatient psychotherapeutic group he is conducting. Comments and additional information coming from his colleagues may prove useful.

Mr. A., in an outpatient group and adjusting well to sobriety, arranged for his alcoholic friend B. to be admitted to the hospital. (Mrs. A. was a member of the wives' group). B. told his psychiatrist that he was Mrs. A.'s lover, a fact her husband did not know. Pursuing the policy that information should circulate as freely as possible, the psychiatrist conducting the group to which Mr. A. belonged was given this knowledge. In time B. communicated to his psychiatrist that he and Mrs. A. had agreed she would tell her husband of the liaison. Having done so, she discussed the affair in the wives' group; Mr. A. ventilated his disappointment and anger in his own group, which required him to perceive that he must have been motivated to overlook what was happening under his nose. (Possible homosexual attachment to B. was not suggested to him either by his fellow-members or by the psychiatrist conducting the group.) This complex chain of disclosure, acceptance and, to some extent, open exposure of significant mutual deceptions

was accomplished without Mr. A. relapsing into drinking. Mrs. A. went through a pregnancy and A. continued sober. Mr. B. broke off contact with the hospital after his discharge.

This careful integration of such different strands of information about each patient and his interactions is achieved through precise and organized staff communication and is a major technical procedure. By meticulous attention to what is going on the staff can comprehend and minimize noxious social entanglements to which alcoholic patients are particularly prone. By their participation in the hospital activities staff members narrow the gulf between them and the patients. Writers sometimes describe such patient entanglements in their hospitals(6), the staff recognizing untherapeutic associations only after they have been established. Perhaps a therapeutic milieu may be said to exist to the extent that such entanglements between patients are entered into by staff members, who at the same time practice professional avoidance of any personal social involvement with patients. Detailed and alert awareness of subtle communications by patients, the essence of good staff coordination, is only useful if the patient is handled with professional responsibility, a condition which was not obtained in some of our notable treatment failures (see report of group meeting following).

The Nursing Staff who are exposed throughout the day to interactions with demanding and socially provocative patients may need much guidance and support, especially if psychiatrically untrained. The use of group methods to train nurses to recognize and utilize therapeutically the excessive emotional involvement engendered by dependent patients has been evaluated in our hospital by Wolff(8). As a didactic procedure the group method is useful; however, nurses with character neuroses are not effectively restrained from disruptive contributions to the patients' milieu experience.

The Psychiatric Social Worker does not duplicate the psychiatrists' function, as in some clinics for alcoholism(9); having her own specific functions, she does not concern herself primarily with the patient's psychiatric status. A careful definition of her role has proved of considerable value: she

deals with the patient's social adjustment, performing a social service function (although in possession of the psychiatric data of his case); but towards relatives she may exert a psychotherapeutic influence.

She interviews the near relative of every patient, thus obtaining an objective psychosocial account, draws the relative into active concern about the treatment process, and she may propose the spouse (if still in the picture) as a potential member of the wives' group. She contacts employers or potential employers, assists the patient with his social disabilities (income tax arrears, failed maintenance payments to divorced wife, etc.). She follows up patients in their outpatient phase, participates with the psychiatric staff in teaching medical students, social workers, clergymen; and she counsels relatives of patients who recommence drinking. She has the responsibility of conveying to the staff the essential social information.

The Occupational Therapist, in addition to enabling patients to be active with creative tasks while in hospital, supervises the patient committees organizing the weekly social club and the hospital shop, and reports back her observations to the total treatment staff.

THE PATIENT'S CONTRIBUTION TO TREATMENT

Central to treatment is the concept that, alcoholism generally responding poorly to an individual approach, group processes have to be initiated and maintained at various levels of hospital activity. Group interactions among patients lead to insights that may enable the patient to modify his patterns of behaviour, especially those contributing to his use of alcohol.

Patient control of aspects of the hospital organization is designed to lead the patient to perceive that he is capable of responsible behaviour, which is in fact expected of him. Doors are not locked, there is no bedtime hour, a newly admitted patient is shown the hospital by a fellow-patient, patients elected by their fellows run the hospital shop, etc. Rules are kept to a minimum, so that patient autonomy in the hospital's social climate can be fostered (with technical participation of the staff to modify the social interactions into a treatment process).

The staff-orientation and coordination, to-

gether with the patient autonomy, are remarked on by patients in terms conveying security. "I'll never want to leave," patients sometimes say in group meetings, or: "It's like a hotel." At the same time angry reproach is repeatedly expressed that not enough is being done, *i.e.*, no active treatments applied of which patients can be passive recipients and the ineffectiveness of which, presumably, patients can demonstrate as soon as they leave hospital. Instead, the patient grasps that it is his own resources which must be summoned to help him in his present strait. The most immediate therapeutic ingredient of the program appears to be the personal relating between the patients themselves. In group and informal discussion they learn what behaviour is appropriate in the hospital, what clinical facts are known about alcoholism, how Antabuse can be useful in helping to cover the next 48 hours. Inpatients throughout their hospitalization are in contact with outpatients, at various stages of rehabilitation, returning to their weekly group meetings or to the social club. During the 23.7 days which, on an average, the patient is in hospital he is acquainted with the way treatment can help him modify the psychological sector implicated in his drinking. Marked behaviour modifications do occur in the hospital; in fact, the staff knows fairly definitely after a few days which patients are not going to be affected by the influences the hospital milieu is devised to provide. These influences I shall attempt to define.

It may be a prerequisite for treating alcoholic patients that the environment be made non-conflictive, non-threatening and non-critical. Otherwise the patient will never lack for an excuse, in which he himself firmly believes, for drinking. However, when tensions between those undertaking his care are minimal, when he is not exhorted or reproached or criticized, the moment comes when he reflects, usually aloud so that he can be heard, "I wish I had a drink now." But his environment is now placid, not haphazardly eventful; the onus can be placed on him to detect why he should be tense, or agitated, or resentful, and need alcohol to sooth such mental discomfort. At this time many patients recognize for the first time that stresses are pre-

texts. With help usually forthcoming from fellow patients, they take the step of initial self-exploration: "These memories of past events, these inner thoughts *do* worry me. They may have played a part in my drinking. I may be able to change my attitudes so that these thoughts don't upset me so much." It is in this mode that the patients bring out in the morning group meetings the extraordinary, humiliating or appalling experiences they had never discussed before. For other participants in the group meeting such self-recognition, and acceptance of responsibility to change, is often an experience evoking reciprocal communications. Rivalries or frank hatreds that have arisen in the hospital between fellow patients are disclosed with strongly expressed affect; the hating individual is enabled to remain in proximity with the hated one, and to explore the strong feelings in both of them. The patient who is clearly recognized by the staff as getting benefit from the hospital is the patient who, through his participation in the group experience, realizes with the impact of insight that the responsibility is his for some aspects of his setbacks in living.

Alcoholics Anonymous brings many people to this realization, as is evident from the famous supplication, "God grant me . . . courage to change the things I can . . ." When psychiatric techniques are used with those alcoholics not responding to self-help in the lay organization, disengagement from external stresses, by providing a therapeutic atmosphere, may be an essential preliminary for arousing in the patient a preparedness to identify inner stresses, and enable him to comprehend that, although shadowy, these inner stresses can be progressively understood, and counteracted through authentic personal engagement with others who have the same problems to contend with.

If both the patient and the staff realize early how complex and subtle a process recovery is, neither will be so cast down by failure in a particular case as to consider further effort futile. The staff finds in the proportion of successful cases sufficient satisfaction to counteract disappointment when patients in whom much was invested are not benefited.

A FAILED CASE AT AN OUTPATIENT GROUP MEETING

Each outpatient group meets 1½ hours weekly, of course always with the same psychiatrist as conductor. The author conducted the meeting reported here, the 23rd of this group, on an evening its regular conductor could not attend. The 8 outpatient members attending were known by him.

The session was dominated by a man who had lapsed in his outpatient attendances after he had started drinking again. He had been drinking that evening. The contributions of this man will be described selectively, to convey how some alcoholics test and strain the treatment procedure. It will be seen that a staff-member got implicated in the acting-out of the patient's pathological dependency needs; he also involved socially a fellow-member, Mr. C.; he monopolized the treatment time that evening; he indicated he had become involved in social difficulties of criminal proportions which psychiatric intervention could not alleviate. Moreover, psychological treatment being mediated by verbal communication, this patient was handicapped by thought processes not uncommon in alcoholic patients (related to emotional immaturity), a self-evasiveness of the double-bluff type. The psychiatrist, for example, knows the patient is being untruthful, but the patient will continue his communications only provided the conversational deception is not challenged. If it is, an angry response is evoked, with the patient removing himself. With mild intoxication, as this patient illustrates, such "insincerity" is exaggerated.

That the lapsed member had been drinking was anxiety-provoking for the others in the group who stressed to another member how unwise it would be for him to discontinue his Antabuse pills, as he was then contemplating. This other member induced more tension by overenthusiastically proclaiming that he would never again take another drink. The lapsed member reminded his fellow members that at Christmas time, in his bid to resume social drinking, he had started to take beers "through Antabuse," while still attending the group meetings. They had been right to try to stop him. He had now been suspended from his job; however, he could get it back at any time. He was not living with his parents, but in the home of a nurse of the hospital, whom he would not name. The doctor pointed out it was contrary to group procedure to make secrets of matters which were of concern to

all members. Some members then said they had heard the lapsed member was living in a nurse's household, admitting they had not brought themselves to discuss this in the meetings although it might have been wiser to do so. The lapsed member then mentioned by name a nursing aide, not professionally trained.

The doctor made the interpretation that the lapsed member appeared to demand, over and above the treatment provided, that the hospital should provide him with a fulltime nurse to look after him permanently. Angrily the lapsed member denied this and said how sorry he was the present doctor was conducting the meeting, and explained tensely that his purpose in coming that night was to request the regular conductor to intercede for him at his job: he had been suspended and was going to be fired. The group members ignored in their remarks that he had at first said his job was secure in spite of his suspension; when the doctor pointed out his inconsistency, the lapsed member rose furiously to leave. The doctor said the lapsed member when angry appeared to remove himself from the scene rather than express in words what he was feeling. The lapsed member said, "Yes, I'm the hell in with you," and sat down smiling. He then accepted interpretations that he was viewing the hospital as a support against harsh employers. His fellow members supported him with descriptions of their occupational setbacks, one member describing with careful detail his annoyance over being fined £15 one Christmas day for drinking a pint of beer when he was a fireman. The doctor took these remarks as indication that the group was inclined to be comforting to the lapsed member; his response was to report that on his way to work each morning he stopped at his mother's house to get a cup of coffee. The doctor again pointed out the strength of the lapsed member's dependency needs: "You seem to need your mother and the nursing aide and your doctor to lean on at present." The lapsed member then said he was in serious trouble; he had expropriated money on his job, using it to buy drink. The nursing aide's husband drank with him.

The nursing aide's position was then taken up. After discussion it was pointed out she had broken a rule of the hospital, one of few, that patients inevitably suffered interference in their treatment when staff members engaged in social relationships with patients. The group became agitated, Mr. D. protesting that every step likely to save the lapsed member from the terrible consequences of his alcoholism was justified. A number of members expressed

how "motherly" they had found the nursing aide while they were hospitalized. But Mr. C. who in trying to contact the lapsed member had taken to visiting his parents, stressed that his parents would very much want to have him home with them. It wasn't as if he had no home. His parents' main wish, in fact, was that he should marry a nice girl so that they could make over their house and all their furniture to him.

The lapsed member burst forth that he hated his father. His father was the sort of man who, if he asked for a chisel and you brought him a hammer, would hit you over the head with it. He offered to leave the nursing aide's house. "She is sick tonight, that is why she has not come on duty." Other members explored how awkward it must have been for her to decide whether she would come to her work at a time he would be attending the hospital, knowing she had gone against hospital procedure in having him lodge secretly with her. The doctor emphasized this point, that psychotherapeutic interactions depend on frankness, not only on the part of patients but also from responsibly cooperating members of the staff, so that all could rely on a secure setting in which to pursue the task of self-understanding.

The lapsed member exclaimed that if frank disclosure was the thing, he could tell the group what had spoilt his life. When he was 5 years old he saw his father slap his mother's face. He "toddled" from the house into a field, vowing never to forgive his father. Since then he had hated his father. That was why he drank. He got himself drunk and then went to his parents' home expressly to show himself intoxicated to his father. It was satisfying to him to make his father angry and distressed. "Do you want to know why I am still single?" he demanded.

This discomfiting question was disregarded, the group instead discussing animatedly the scene of parental strife just described. Mr. D. said he disbelieved the mere witnessing of a smack could lead to alcoholism. The members detailed occasions when they themselves had struck their wives, especially when not sober, indeed, how their wives had thrown coffee cups, *etc.*, at them, but no grudges had been borne. The lapsed member was told his parents had forgotten that slap a long time ago. He was urged to forgive his father; to go further and, after confession, to beg his father's forgiveness for the hatred he had harbored. Mr. C. pointed out that while the drunkenness was intended to wound the lapsed member's father, his mother had told Mr. C. that each time her

son appeared drunk "you were sticking a knife into her heart."

This reference led the doctor to remind the group that the lapsed member had wanted to consider with them why he had remained single. The lapsed member said that when he was a little lad, at the time of the slap, he vowed to wait for his father to die, when he would care for his mother himself.

The group exclaimed with surprise over this wrongheadedness. But the lapsed member persisted: he would never marry, instead intending to devote himself to his mother. Mr. C. was emphatic that the mother desired her son married. The doctor interpreted that Mr. C., like the mother perhaps, might be concerned how the lapsed member met his sexual needs.

The lapsed member began to convey how virile he was, his verbal excesses causing anxiety in the group members. He asked the doctor, "Has your car got a big enough back seat?", offering to have the doctor meet the ladies he knew. He made the group smile participatively when, unabashed by their restraints, he leant forward to demonstrate to the doctor his tie, a red one with the earth, Mars, Venus, *etc.* on the public side but on the inside, when the tie was folded open, a pin-up girl. This assertion of sexual freedom was not interpreted as miscarried rebellion against an authority presumed to be condemnatory of sexuality; the entire group was now participating in the amused assertiveness, until Mr. D. explained to the lapsed member that precisely what was happening was what his parents might fear, his going with prostitutes. But they were in favour of his having a decent girl.

As the meeting closed the lapsed member said he would obtain Antabuse tablets on leaving and next day he would visit his parents, to tell his father of the hatred he had felt since childhood. However, he did not return to later meetings. He had come close to recognizing that a childhood hatred of his father was affecting his total behaviour; if he could modify this, his chances of being able to stop drinking for longer periods would improve, and even his mode of sexual activity might alter. In this case, the impetus to carry over the group benefits into social action did not take place. The point of treatment failure can be defined. Perhaps no further treatment occurred because his work problems became intolerably pressing, certainly his involvement with the nursing aide adversely complicated treatment. Not being sober may have blunted his grasp, as it facilitated his communication.

EXTENT OF SERVICES PROVIDED

In the first year, 180 patients were treated with brief hospitalization (average stay of 23.7 days) followed by outpatient small-group psychotherapy conducted by a psychiatrist. An additional 105 patients presenting during the year were not admitted, but alternative disposition or treatment arranged.

Total admissions during year	180
Re-admissions	28 (15.6%)
In direct contact	105 (58.3%)
In indirect contact	32 (17.8%)
Out of contact	38 (21.1%)
Deaths	5 (2.9%)

Direct contact means that the patient had continuously attended for treatment, or attended some other hospital activity (e.g., social club) so that he was seen personally and his current status checked. *Indirect contact* means that a relative or close associate in immediate touch with the patient provided a report on his status. It will be seen that contact was not kept with one-fifth of the patients admitted during the first year; many patients did not have addresses when admitted and were not employed. To maintain follow-up with this group would require considerable exertion by specially appointed staff.

Eighteen (10%) of the patients were women.

Four categories of treatment outcome were adopted in making assessment of progress: sober, improved (a judgment that the patient was drinking less, was now working regularly, had returned to his estranged spouse, etc.), unchanged or not known:

Sober	87 (48.3%)
Improved	26 (14.4%)
Unchanged	39 (21.7%)
Not known	23 (12.8%)
Deaths	5 (2.9%)

After a year, 62.7% of patients were known to have benefited from the treatment. Some had been sober for over a year when the follow-up was completed, some abstinent only for a few months. There were already 4 outpatient closed groups in progress, the first having met for 53 sessions when the review of the first year was made; in addition

the open group and the wives' group met weekly.

As well as the treatment service provided, contribution has been made to change in general attitudes towards alcoholism in the community. Seminars have been held for medical students, social science students, the clergy, personnel managers, probation officers and general medical practitioners. A close association with the local branches of Alcoholics Anonymous is maintained. The Advisory Committee of community leaders appointed by the Administrator of the Cape Province is an active link between the hospital and the community. Public organizations are addressed by members of the hospital staff, so that knowledge and experience can be spread to agencies and individuals in a position to be helpful to the alcoholic.

SUMMARY

1. A form of hospital treatment for alcoholism, providing short hospitalization followed by prolonged outpatient treatment is described.

2. A therapeutic hospital milieu results from techniques facilitating patient interaction; treatment intervention by the staff is also coordinated through group methods.

3. The patient effects identifications with fellow-patients, his re-socialization commencing with his recognition that inner stresses, which he can be helped to modify, have contributed to his drinking.

4. Small group techniques are an effective means of outpatient psychotherapy when the patient is beginning a sober working adjustment and forming new social relationships.

THE USE OF STIMULATING DRUGS

DAVID W. SWANSON, M.D., AND JACKSON A. SMITH, M.D.¹

The pharmacologic approach to the treatment of the depressed patient has recently been very active. The increasing number of new preparations has been accompanied by enthusiastic comments: "simply dissolves symptoms of depression . . . with recovery or marked improvement reported to occur promptly in 70-85% of cases"(1); "ameliorates symptoms of depression . . . often capable of normalizing"(2); "anti-depressant without euphoriant effect"(3); and "alleviates the depressive state but does not act as a stimulant"(4).

To the older readers these statements must provoke nostalgia. It was in 1936 that hematoporphyrin seemed "to produce activation, in some cases mental stimulation and in others general improvement"(5). And in 1941 Metrazol "in nearly 73% brings about favorable change classifiable as recovery or as social remission"(6).

In searching for effective antidepressant drugs the most common source has been the cerebral stimulants. In utilizing these stimulants the inference drawn seems to have been that the emotionally depressed patient has a depressed nervous system; unfortunately this assumption still lacks confirmation.

The term stimulant is not currently popular when applied to the new antidepressants. However, if one accepts the definition of a cerebral stimulant as a substance that "exalts the functional activities of the brain"(7), such alter-designations as "psychic energizer," "thymoleptic," or "normalizer" seem less separate.

EFFECTS ON THE CENTRAL NERVOUS SYSTEM

Investigation for effective CNS stimulants has been a difficult one, with undesirable effects more common than desirable ones. This is evidenced by the less recent stimulants such as picrotoxin, metrazol, strychnine and camphor which in the unanesthetized human produce excitation only at the convulsive dose(8). They have been used

in the treatment of depression but were abandoned due to this complication; or conversely used because they did produce a convulsive episode.

Some other preparations capable of producing convulsions at higher than the therapeutic dose are cocaine and anticholinergics such as atropine(8, 9). Both have been prescribed to stimulate the depressed patient.

Seizures have been reported with imipramine (Tofranil) and the monoamine oxidase inhibitors, but fortunately are rather rare occurrences(10, 11). On the other hand, the recommended dosage of newer drugs may be increased in an effort to enhance their effectiveness; when this occurs, the convulsive threshold may be approached.

The usefulness of the stimulants has also been limited by their multiplicity of actions. This has been experienced by the laity when they take coffee, tea or cocoa in excess and become restless and have their sleep disturbed. Similarly the use of the amphetamine group has been limited clinically by early restlessness and tremor.

The newer antidepressants can produce insomnia, irritability and nervousness, but these side effects occur in less than 10% of patients(12-15). The fact that these side effects occur at all may be due to the structural similarity of these drugs to the earlier introduced stimulants.

For example methylphenidate (Ritalin) and pipradol (Meratran) contain the phenethylamine skeleton just as does the amphetamine group. And the monoamine oxidase inhibitors are hydrazine analogues of these sympathetic amines(16).

EFFECTS ON OTHER BODY SYSTEMS

Aside from the direct effects of stimulants on the nervous system, there are actions affecting other systems. These toxic or side effects frequently are listed at the end of therapeutic reports. This may be analogous to the small print on a legal document, important but unpleasant to consider. Actually this brief description of side effects is justi-

¹ Illinois State Psychiatric Institute, Chicago 12, Illinois.

fied in many drug reports since they may only be an annoyance to the doctor or the patient. This is true of the cardiac arrhythmias and hypo- and hypertensive effects with mild excesses of caffeine and amphetamine(8). Orally the mild cortical stimulants methylphenidate and pipradol seldom produce more than subjective discomfort in the cardiac patient if they are used with caution. Added caution should be exercised with intravenous methylphenidate(12, 17).

With the many new antidepressants made available to the clinician it behooves him to observe his patients carefully for signs of toxicity. It is dubious whether we yet know the range or intensity of side effects, since these can only be determined by prolonged observation. Certain of the monoamine oxidase inhibitors have shown severe degrees of toxicity. Iproniazid (Marsilid) a charter member of the energizers and beta-phenylisopropyl hydrazine (Catron), a more recent arrival are hepatotoxic compounds or produce visual complications(18, 19).

Other members of this group, phenelzine (Nardil), nialmide (Niamid) and isocarboxazid (Marplan) reportedly produce orthostatic hypotension, light-headedness and syncope in 10-20% of cases. Constipation, nausea, edema, hepatotoxicity and drug rash are much less frequently seen(11, 13, 14, 15, 20).

Imipramine and benactyzine have side effects that are atropine-like. This is expected with benactyzine which is an anticholinergic that in approximately 10% of cases produced mild complaints of dryness of the mouth, drowsiness or dizziness at presently recommended dosages(21). With dosages of 250 mg. daily nearly all patients receiving imipramine complained of dryness of the mouth and sweating(22). At lower dosages 10-20% note these. Less frequent effects are tremor of the extremities, dizziness, blurred vision, constipation and hypotension(23). Agranulocytosis and skin reactions have been noted rarely(10, 24, 25).

UNTOWARD PSYCHIATRIC EFFECTS

Since stimulants are not specific, they conceal rather than relieve; and in the end the depressed patient's state may be aggravated. Principally, because observations indicate that it is not possible to stimulate

the central nervous system for a long period without the heightened nervous activity being followed by depression, proportional in degree to the intensity and duration of the stimulation(8).

This leads to the problem of psychological habituation. Patients with a low tolerance for frustration may take more drug to avoid the "let-down" following the interval of stimulation.

An example of the subtleness of a drug's addictive potential was demonstrated in the later part of the 19th century when cocaine became well known as a stimulant and euphoriant. Its severe addictive qualities escaped the recognized acuity of physicians Freud and Hallstedt when it was first put into use. Personal disaster came near to these early proponents of this drug which seemed to selectively elevate mood. Freud was an active proponent and Hallstedt an addict, fortunately a temporary state for both(26, 27).

It is pertinent to remember that there are over 25 compounds related to amphetamine marketed for use as CNS stimulants, bronchiol dilators, vasoconstrictors and appetite depressors. Undesirable, as well as desirable, effects must be considered in the use of all these compounds. That habituation may result is shown in the following cases:

Case 1: This 31-year-old woman had been taking an amphetamine (Auban) for 4 years ("first to lose weight and then I couldn't stop"). She progressively increased the dosage and at the time of admission was taking 70 mg. of methamphetamine and 420 mg. of phenobarbital daily in this form. Approximately 4 months prior to admission she was observed to work in her home at an exhausting pace and at all hours of the day and night. Mild ideas of reference appeared which increased with the development of paranoid delusions, hallucinations, forgetfulness and agitation. She was hospitalized and these acute symptoms cleared in 3-4 days. It was noted after her first home visit that she was somewhat agitated, confused and exhibited slurred speech. She admitted consuming considerable quantities of the drug again.

Case 2: This 19-year-old woman had been taking phenmetrazine (Preludin) for 18 months prior to admission. The drug was initially used as an adjuvant to weight reduction. She gradu-

ally increased the dosage to 15-18 tablets daily. Some 5 months prior to admission this previously ambitious, well-controlled student was observed to become loud and abusive over trivial occurrences, failed at work and made a suicidal attempt. One month prior to admission she had explosive temper tantrums, was physically abusive to her mother, became very paranoid and was writing bizarre things. She then made a suicidal attempt by ingesting 100 one-half grain phenobarbital tablets. She was found, brought to the hospital and treated on the medical ward for 3 days for "acute barbiturate intoxication." When transferred to the psychiatric service, she was cooperative and composed. She had some feelings of guilt but the overt psychotic symptomatology mentioned above was not observed.

Since an abstinence syndrome has not been clearly ascertained with the amphetamines, the academic designation of addiction (habituation, tolerance and withdrawal) is a debatable point. But, it has been observed that individuals habituated to the amphetamine series are at least as resourceful in obtaining the drug as the chronic alcoholic and some addicts (28).

Finally, the antidepressants may produce clinical psychiatric symptoms. The ability of the amphetamine series to produce a clinical syndrome often indistinguishable from schizophrenia, in the acute phase, has been described previously (29, 30). The two cases of amphetamine habituation described in this paper are typical of these reports.

Hypomania may be seen with imipramine and the monoamine oxidase inhibitors; and in the former the hypomania has reportedly persisted after discontinuing the drug (31).

COMMENTS

It is evident that the new antidepressants are chemically related to those previously used. There are similarities in structure between atropine, amphetamine, acetylcholine, histamine and the newer stimulants.

By the manipulation of side-chains and other structural changes, the pharmacologist has presented the clinician with these new antidepressant drugs. Though modes of action are unclarified they have proved attractive because post drug "let-down," severe agitation and convulsions have not been prominent in the suggested therapeutic range. The need for stimulants with fewer

side effects is undeniable, but the therapeutic enthusiasm recently shown has yet to stand the test of time (32, 33).

Finally, the ease of treating the depressed patient with a medication possessing no great risks, but uncertain effectiveness, has inherent danger. It may lull the clinician into lessening his precautions against suicide and the application of more proven therapies, *i.e.*, electroconvulsive therapy and hospitalization. The result may be an actual increase in morbidity and mortality. Thus the greatest hazard is not so much the side effects as the lack of proven clinical effectiveness of these compounds.

DEPRESSION IN THE PSYCHOSES OF MEMBERS OF RELIGIOUS COMMUNITIES OF WOMEN

SISTER M. WILLIAM KELLEY, I.H.M.¹

A survey of the incidence of hospitalized mental illness among members of religious communities of women in 1956(1) indicated that there had been a considerable increase since an earlier investigation in 1935(2). A comparison of the figures for 1935 and 1956 not only reveals a very significant ($P < .001$) increase over the 20-year period, but a comparison of these figures with the corresponding statistics for women in the general population who were hospitalized for mental illness shows that the rate of mental illness among sisters has increased at a significantly more rapid rate ($P < .02$) than among the latter population. It should be noted, however, that the rate is still considerably lower among religious.

There are a number of objections which can be made to the reliability of this kind of survey and to conclusions based upon it: 1. Statistics on the subject of mental illness are notoriously misleading, especially for comparative purposes; 2. The apparent increase of mental illness among religious is due to earlier and/or more frequent recognition of problems which have always existed in the same proportions; 3. There are more facilities available now, hence more religious are hospitalized. While it is true that "fads" in diagnosis, inconsistencies in nomenclature, and non-reporting hospitals do throw statistics on mental illness into serious question, there is no reason to accept the suggestion that these have affected one group differently from the other. Therefore, the present investigation was undertaken on the assumption that there has been a real increase in mental illness among sisters and that it is statistically significant.

The method used was determined in large part by the nature of the material available. A Catholic mental hospital which regularly treats a number of sister-patients allowed the use of the case files of 50 religious who had been or were currently hospitalized for

a variety of mental disorders. The cases were drawn according to diagnosis, in numbers proportionate to the distribution of diagnoses in the 1956 survey. The completed sample included: 25 schizophrenia of which 13 were paranoid; 8 manic-depressive of which 4 were depressive reactions; 5 involutional psychosis; 2 cerebral arteriosclerosis; and one each of senile psychosis and chronic alcoholism.² The analysis of these histories was almost completely unstructured, not so much by design as by their uneven quality and their relative completeness or incompleteness. The histories were searched for any appearance of regularities or patterns of relationships, in the hope that there might be isolable some uniformities in family background or work history or symptomatology which might constitute or reflect causative factors in the sisters' breakdowns.

The report of this investigation confirms and underlines the commonplace that case records are still not very helpful in the attempt to unravel the etiology of mental disorder. In the case at hand, one can presume that the informants were sometimes led to conceal certain data from psychiatrists or hospital personnel because they were ashamed of mental illness, or they feared to put their religious communities in a bad light, or they simply had not been geared to be aware of possibly relevant behavior

² Fortunately, the decision to select on the basis of diagnosis produced a sample which was well-matched with certain other characteristics reported in the 1956 study, chiefly that of the patients' occupation prior to hospitalization. Twenty-eight per cent of the sample, as compared with 27.7% of the survey population were engaged in domestic tasks. (At least 5 of these 14 domestics had begun as teachers or hospital personnel but were unable to keep up with professional demands.) When one considers that sisters in domestic service constitute no more than 4% of all sisters in the United States, the rate of mental illness among them is astonishing and provocative. Forty per cent of the sample (50% of the survey) were teachers; 16% (14%) were nurses or other professional hospital personnel; 10% (5%) were cloistered; 6% (5%) were clerks or other.

¹ Immaculate Heart College, 2021 N. Western Avenue, Los Angeles 27, Calif.

in the patients' background. The case histories reported by these informants are consequently impoverished. This is especially unfortunate, because we have in religious communities a sufficiently homogeneous body, sharing a common system of values, formed by somewhat standardized processes, and relatively easy to control, and it should be possible to learn much of value about mental illness in general from a careful study of this group.

The preponderance in the 1956 survey of disorders in which depression commonly occurs led to the suspicion that self-accusatory depression might figure prominently in the disorders of a majority of mentally ill religious. It must be admitted that the case histories did not yield enough clear data to warrant formulating this as a hypothesis, but the following summary of tabulations, relationships, exclusions, and impressions are submitted as evidence leading to and in support of the proposition that psychotic sisters tend to be symptomatically like one another, especially with regard to manifestations of depressed states.

There was so little reported on childhood experiences in the histories that one would conclude that the patients had had no childhood, and certainly there was nothing of any theoretical significance in this area. There were, however, a number of conditions which appeared in these histories with notable frequency and which, as expected, crossed diagnostic lines quite indiscriminately. For instance, in 30 of the cases the informants volunteered information which indicated that the onset of the patients' illness was of considerable duration—averaging over 6 years. There are a number of considerations which should temper any inclination to generalize from such ambiguous data; nevertheless, in the context of some extraordinarily fragmentary histories, any regularity may deserve more rather than less attention than one would be inclined to attach to it.

If senile and arteriosclerotic cases are excluded, the average age at first hospitalization was 41. For schizophrenics, who form the largest portion of the sample, it was 38. Looked at in another way, this means that the sisters involved had spent, on the average, from 17 to 20 years in their communi-

ties before being hospitalized; and, if we can judge from the histories, the 5 or 6 years preceding hospitalization were increasingly stressful for the patients and their companions, and increasingly unproductive. The average hospitalization for the total sample was 4 years 4 months, although the high incidence of paranoid schizophrenics (whose average hospitalization was 6 years 8 months) creates a deceptively high average. In view of the fact that 35% of the sample had been previously hospitalized at least once, and another 25% more than once, the average period hospitalized during a lifetime for the sisters in this sample will be predictably very high.³

While these data might not in themselves seem to be specifically related to the proposition that the psychoses of religious tend generally to include manifestations of severe depression, they constitute a quantitative backdrop to the context of the religious life in which these patients live, and when viewed in this perspective they may assume new relevance. The following portion of the article combines some information from the 1956 survey and some material from the case histories with some insights based on personal experience of the religious life. The significance of the 4 points issuing from the combination and the conclusion based on them can be tested, presumably, only by further experiential observation.

1. Sixty-four per cent of the case records used in this study contained specific reference to at least one of the symptoms included—not altogether arbitrarily—under the term self-accusation, namely: scrupulosity, a sense of worthlessness, a sense of failure, the desire to be destroyed. An additional 12% were described without further elaboration as being "severely depressed" prior to and during hospitalization.

2. The rates of hospitalized sisters per 100,000 in each of the specified occupations in the 1956 survey were: domestic, 3042; cloistered, 645; teachers, 420; professional hospital personnel, 228. As has been pointed

³ Here again the sample is notably like the universe from which it was drawn. In 1956 the average age at first hospitalization was 44; the average length of hospitalization was nearly 5 years; 48.4% had been previously hospitalized for mental illness.

out, the occupational distribution in the present sample is almost identical with the survey distribution, and it can be assumed that these rates are more or less stable. It may be no more than an interesting coincidence that the rates of psychosis increase as we move from the most totally absorbing and "distracting" occupations to those which leave the greatest freedom to the mind.

3. Asceticism, the practice of systematic self-denial for the purpose of attaining a higher ideal, is an integral part of the religious life. In the interest of ascetical practice, exercises in deliberate and controlled self-examination and introspection are institutionalized in the religious life. If these exercises are undertaken without prudent direction and/or by unstable, immature persons, they can easily and insidiously develop into gross depression. The case histories strongly suggest that such depression becomes a stage in a circle of abnormal manifestations which may eventually include the delusions and hallucinations reported in 60% of these cases.⁴

4. A certain amount and kind of insecurity is inevitable in the structure of the religious life. Being uprooted overnight from everything to which they have become accustomed is for some a trauma which is never outlived. The trappings of the life remain for them always uncertain, unreal, painful, and this is all the more difficult, discouraging, and depressing because it is not supposed to be so. Unless or until a person has developed considerable psychological and moral strength and stability, some of the demands associated with practicing the vows of poverty, chastity, and obedience can constitute an over-rigorous

program. Because of the organic structure of the religious life, failure or inadequacy, even in morally neutral matters, is often interpreted to be a matter of moral guilt, and repeated failure or experience of inability to meet standards intensifies depression.

CONCLUSION

This report is not intended to suggest that psychotic religious, or religious in general, are more depressed than other occupational or social classes, but to outline some possible reasons, specific to their life, why those who are depressed become so. Great stress is laid in religious life on hard work, high productivity, and "success" in the strictly religious and spiritual aspects of conventual life as well as in the "active" or professional works which they undertake. (The traits of the "American character" are quite faithfully mirrored in American religious communities.) In addition to these cultural influences, certain immature or poorly instructed religious are plagued by the suspicion that every failure is a sin, and for this reason their mental disturbances themselves become a circularly reinforcing cause of depression. The early onset and lengthy course of their disabling disorders, and the high rate of recurrence, further intensify their depression.

Considering the carefully structured character of religious life, it would seem that more careful selection among those who apply for permission to undertake the life, joined with precise and accurate moral and psychological instruction of those admitted could do much to reduce appreciably the abnormally depressed states among religious.

⁴ It would be illogical and mistaken to conclude here that the self-examination and introspection are faulty methods to be employed in pursuit of an ideal; there is a great body of evidence to the contrary. What is implied is that they must be exercised wisely and under wise direction.

MURDER AS A REACTION TO PARANOID DELUSIONS IN INVOLUTIONAL PSYCHOSIS AND ITS PREVENTION

JOHN LANZKRON, M.D.¹

Murder of the spouse as a reaction to delusions of infidelity and/or delusions of persecution is an ever present danger in patients suffering from involutional psychosis, paranoid type. In order to illustrate the malignancy of this clinical picture, I would like to relate excerpts from case records of patients charged or indicted with Murder, first degree, and committed to Matteawan State Hospital for the Criminal Insane:

Case 1: This 43-year-old white male patient of pyknic habitus and average intelligence was never in conflict with the law until he was arrested for homicide. For several years he had been sexually impotent and suspicious of his wife's infidelity. He described progressive distrustfulness of her to the point where he would inspect her genitalia to see if she were sleeping with other men. Finally, he was so preoccupied with his delusional system of her unfaithfulness that he was unable to work, lost his job and his wife separated from him. While appealing to her to return to live again with him, he shot her because of her refusal.

Case 2: This 55-year-old white male patient strangled his wife with a chain. Patient had become sexually impotent for about a year preceding the crime, and had delusions about poisoning by his wife. For several months prior to the crime he expressed ideas of infidelity and blamed the loss of sexual interest on his wife's nagging. His psychosis was characterized by ideas of infidelity, ideas of persecution directed against his wife, ideas of poisoning, misinterpretation of real occurrences and somatic complaints. His homicide was a reaction to his paranoid ideas directed against his wife.

Case 3: This 59-year-old white male patient was always shy and retiring; he became depressed in December, 1959. This depression led to his retirement from the postal service; he sold his home on August 1, 1960 and moved to a new residence. He became increasingly more depressed and withdrawn. Following an argument with his wife he strangled her and then attempted to commit suicide by turning on the gas but was found by the police and arrested. In this case the diagnosis was involutional psychosis, melancholia.

Case 4: This 52-year-old white male patient had been previously hospitalized because of depression, jealousy and ideas of infidelity. On January 13, 1957 he stabbed his wife to death and then planted the knife into his abdomen in two places. Patient's psychosis was characterized by ideas of infidelity and ideas of persecution. His homicide was a reaction to his delusional system. He claims that his wife wanted to put him in a psychiatric hospital to get rid of him, while, at the same time, she was showing interest in younger men.

Case 5: This 69-year-old white male patient showed evidence of mental illness for the first time in 1937, at the age of 46. It was characterized by ideas of infidelity, ideas of reference, misinterpretation and somatic complaints. Patient separated from his wife and finally obtained a divorce in December 1954. He remarried within a short period of time, again developed ideas of infidelity, ideas of poisoning and mild ideas of persecution with evidence of illogical thinking. He continued to express many somatic complaints. He had ideas of infidelity which he based on very trivial happenings but he still seems convinced that they were proof of infidelities on the part of his wives. At the age of 63 he finally killed his second wife by strangling her with his bare hands. It was felt that while there had been recurrent periods of depression, the underlying mechanisms belied a deep-seated schizophrenic psychosis which again became acute in the involutional period to such an extent that the patient killed his wife as a reaction to his delusions of infidelity and persecution.

Case 6: This 62-year-old white male patient first began to show mental symptoms early in 1953, at the age of 55. His psychosis had been characterized by preoccupation, seclusiveness, restlessness, lability of the emotions, ideas of reference, irritability and depression. He was twice treated with ECT and showed marked improvement. When he was discharged from the hospital, he apparently was in a remission from his involutional psychosis but there were still residuals in his mental condition with depression and irritability. Soon again he voiced ideas of reference and delusions of persecution towards his wife. Finally, at the age of 58, during an argument with his wife, he killed her with a knife. The diagnosis of involutional psy-

¹ Assistant Director, Matteawan State Hospital, Beacon, N. Y.

chosis, paranoid and depressive features had to be continued.

Case 7 : This 57-year-old white female patient has a history of longstanding abnormalities of personality traits and habits which developed into overt insanity about 8 years ago, about the time of her menopause. Her psychosis had been characterized by depression, agitation and delusions and culminated in the murder of her husband, because of her belief that he had cancer. She had delusions of persecution and ideas of reference.

Case 8 : This 45-year-old colored female patient had an apparently normal childhood and adulthood development. Patient had a hysterectomy in 1944. Over a period of a year from the beginning of her menopause, she gradually developed a psychosis characterized by hypochondriacal complaints, ideas of infidelity and paranoid ideas concerning her husband, culminating in the murder of her husband. She admitted that about a year before the murder, she thought that people were staring at her and she admitted auditory hallucinations, claiming that at the time of the murder she thought there were other people hiding in the house who were talking to her.

These are some of the more characteristic cases of homicide which occurred as a reaction to delusions of persecution and/or delusions of infidelity in patients suffering from an involutional psychosis. Many other cases were committed by Court with the charge or indictment of assault, after they had unsuccessfully tried to kill their marital partner as a reaction to their delusional complex of ideas. It is noteworthy that the majority of the male involutional patients committed for murder or attempted murder of their wives as a reaction to delusions of infidelity and/or persecution are of Latin cultural background with a high respect for

the inviolability of the marriage vows as far as the women are concerned. In comparison with the male patients, among 86 women committed for murder (with a total adult female population of 200), only 3 were diagnosed as involutional psychosis and none of them were of Latin cultural background. In all of our patients the homicidal act was preceded for many months or years by a slowly developing involutional psychosis with ideas of persecution and/or infidelity.

Recently much has been published about the prevention of suicide but nothing so far about prevention of homicide. We have to be on our guard if an involutional patient expresses paranoid ideas about his spouse. The forebodings which always exist should not be ignored. These patients should be hospitalized and kept under strict surveillance if there is a serious, well-founded fear of the marital partner threatened by the paranoid patient. Prevention is better than treatment.

CONCLUSION

Eight short case histories were presented of patients admitted to Matteawan State Hospital for the Criminal Insane charged or indicted with murder, first degree, occurring as a reaction to paranoid delusions of an involutional psychosis. In all of these cases, forebodings of the malignant nature of patient's mental illness were present. This would indicate that these patients harbored potential homicidal tendencies for a prolonged period of time. A patient in the involutional period with potential homicidal tendencies as a reaction to paranoid delusions, should be hospitalized as a preventive measure as early as possible, the same as is done with potential suicidal patients.

A QUANTITATIVE STUDY OF CHLORPROMAZINE AND ITS SULFOXIDES IN THE URINE OF PSYCHOTIC PATIENTS

CHIEN LI HUANG, M.D., PH.D., AND ALBERT A. KURLAND, M.D.¹

INTRODUCTION

After the introduction of chlorpromazine in psychiatric treatment in 1951(1) many clinical reports followed, attesting to its efficacy. These data are summarized in a number of recent reviews(2, 3, 4), but a series of issues remain unresolved. These are: (a) the difficulties in determining adequate dosage levels without any means other than clinical observation(5); (b) the duration of maintenance of the patient who has shown a favorable response to this type of treatment(6, 7, 8); (c) the factors which influence the variations in the rate of regression when such patients are taken off medication(9, 10); and (d) the introduction of more potent congeners(10) of chlorpromazine has re-emphasized the need for information relative to the metabolism of these compounds.

A review of the literature indicates that relatively little is known concerning chlorpromazine metabolism in man although there are a number of studies on the metabolism of the drug in animals(11, 12, 13, 14, 15, 16) in which different metabolic patterns have been demonstrated(14). Salzman and Brodie(16) found a negligible amount of unchanged chlorpromazine and about 5% of sulfoxide in the urine of 2 patients receiving 900 mg. of chlorpromazine administered orally. Berti and Cima(14) reported finding 20% of the administered dose in the urine of man following a single oral dose of 100 mg. of chlorpromazine, but the nature of the metabolites was not examined. They also reported finding over 90% of the chlorpromazine metabolites in the urine of man as sulfoxides; however, Posner(17) suggested that phenol formation represents a major pathway of metabolism of the drug. Nadeau and Sobolewski(18) carried out studies relative to the conjugated forms. They reported that following chemical or enzymatic hydrolysis 10 to 20% of the con-

jugated fractions was recovered in the urine of subjects receiving 75 to 300 mg. of chlorpromazine daily. Lin, *et al.*(19) demonstrated glucuronic acid on paper chromatograms after the enzymatic hydrolysis of the urine. Fishman and Goldenberg(20) reported detection of 6 sulfoxides plus other unidentified polar metabolites, and Haynes(21) found 5.5 to 9.0% of the ether extractable metabolites as bound chlorpromazine and free and bound chlorpromazine sulfoxide in the urine of 4 patients receiving daily dose of 200 mg. and 800 mg. chlorpromazine for 4 to 11 days.

As a result of this survey and the considerations indicated above an experimental study^{2, 3} was initiated: 1. To determine the total amount of free chlorpromazine and its sulfoxide in the urine of chronically ill, psychotic patients being maintained on chlorpromazine; 2. To determine the changes occurring in the levels of free chlorpromazine and its sulfoxide in the urine of patients when medication is discontinued. Are there differences between excretory patterns of those patients who regress quickly and of those patients who maintain their improvement for longer periods of time? 3. To determine when treatment with chlorpromazine is reinstituted what effect it has on the pattern of chlorpromazine metab-

² This study was made possible by a research grant (MY-3967) from the Department of Health, Education and Welfare, Public Health Service, National Institute of Mental Health.

³ The authors wish to express their appreciation to Dr. Samuel Bessman, professor of pediatric research and associate professor of biochemistry of the University of Maryland Medical School for consultation and help with many of the technical problems in developing the analytical procedures, and to Misses S. Chen and D. Kremen for their technical assistance. Thanks go to Dr. I. Derby for the analysis of urinary creatinine and to Dr. E. J. Van Loon of the Smith Kline and French Laboratories, Philadelphia, Pa. for the supply of chlorpromazine and its sulfoxide standards. Appreciation is also acknowledged to Dr. Bruno Radauskas, Superintendent of the Spring Grove State Hospital for making the clinical facilities available.

TABLE 1
Chronically Hospitalized Male Schizophrenic Patients

PATIENT	AGE	HOSPITALIZATION	BEHAVIORAL PATTERN IN REGRESSION	BEHAVIORAL PATTERN IN REMISSION	DRUG* FREE	MSRPP RECEIVING** TREATMENT
1	25	6 yrs.	Smiles in hostile manner. No truth to his statements; delusional, hallucinated. Pushes other patients. Needs seclusion for his own protection. Confused, resistive.	Helps with ward work; understands what is said; quiet and cooperative; occasional visits home on Sundays. Tends to be more withdrawn.	59	58
2	19	3 yrs.	Euphoric and hyperactive, alternating with depression, physical complaints, starts fights, nervous movements of fingers.	Has ground parole, friendly, goes home on weekends; appears much more at ease.	26	19
3	53	28 yrs.	Seems miserable, unhappy, apathetic, withdrawn from all activities, hallucinated, removes clothing, autistic behavior, irritable, restless.	Is tolerant of other patients; less delusional and irritated; relaxed and comfortable	30	32
4	37	9 yrs.	Confused and slow; withdrawn, hallucinated, preoccupied; becomes a feeding problem in response to a delusion of "something going on inside."	Less delusional, ground parole, will talk with other patients, helps with ward chores and is cooperative to ward routines.	27	27
5	41	16 yrs.	Hallucinated, suspicious, delusional and restless, autistic, dissociated, appears very uncomfortable and sleeps poorly.	Ground parole, relaxed; not so anxious; friendly with everyone—very little delusional content expressed; seems to sleep and eat well.	50	26
6	40	22 yrs.	Withdrawn, restless, seclusive and almost mute; answers are irrelevant; paranoid ideation is expressed, becomes aggressive; will elope.	Answers questions meaningfully; helps with ward work; cooperative to ward routines and has ground parole.	64	31
7	48	4 yrs.	Confused, mutters to himself, goes into a catatonic stupor, is agitated, refuses to drink or eat or take care of his personal hygiene, gives negative answers to questions.	Becomes cooperative to ward routines and is no management problem.	38	41

Structured in this manner in order that the test design not be exposed to the rating psychologist.

olites excreted in the urine : (a) when compared to their previous pattern and (b) when compared to the degree of stability maintained without the drug.

METHOD

A group of 7 hospitalized, male schizophrenic patients who were being maintained on either chlorpromazine or one of the phenothiazine drugs and housed on the same ward was selected for this study (Table 1). Patients Nos. 1, 2, 3, and 4 were being maintained on chlorpromazine prior to the study. Patients Nos. 5, 6, and 7 had been on trifluoperazine. The group was limited to 7 since the resources available for the chemical studies were very modest and the studies were highly exploratory in character.

Prior to the study evaluations of the patients' clinical status were obtained during several interviews with the research psychiatrist. Data on their behavioral patterns were recorded from nursing notes and interviews with the ward personnel who had known the patients for some time. The patients were also rated by a psychologist working blind utilizing the Multidimensional Scale for Rating Psychiatric Patients (MSRPP) (22). This is a factor-analyzed

scale yielding scores on several dimensions of psychopathology, including a total morbidity score.

Then the patients' previous medication was discontinued. The drug free phase was allowed to proceed until the patient began to show signs of deterioration. This was usually characterized by increasing discomfort and accentuation of his symptomatology. At this point drug therapy with chlorpromazine was instituted in all cases (Table 2).

CLINICAL OBSERVATIONS

These were made according to the following plan : the patients were seen during the first year of the study on the average of once weekly ; the same nursing personnel remained assigned to the ward and were very familiar with the patients and the characteristic fluctuations of their behavior ; and the same psychologist carried out the ratings.

The decision at which point the patient's drug free period (Table 2) should be terminated resulted in a division into two samples : (a) Nos. 1 and 2 in whom the decision was relatively easy since they expressed themselves in increasing outbursts

Notes : (a) Originally the combined quantity of CP and CPO was determined.

(b) Subsequently CP and CPO were determined separately according to the Salzman and Brodie method(16) as modified by these Investigators.

(c) The last technique utilized for CP and CPO was determined by quantitative paper chromatography.

(d) Patients Nos. 5, 6, and 7 had been on trifluoperazine prior to being placed on this study.

* Average excretion was obtained by taking the number of determinations during the period of the specific dosage totaling them and dividing by the days on the specific dosage.

of hyperactivity, irritability, conflicts with other patients, and caused increasing difficulty of the ward management (Table 1); (b) Nos. 3, 4, 5, 6, and 7, who were much more difficult to determine since their regressive patterns were not as dramatic, but were a slow drift toward increasing psychopathology (Table 1). In this latter group it took at least 2-3 weeks to make a decision. Once the impression had been obtained that the patient was displaying signs of increasing discomfort, *i.e.*, responding more markedly to delusional and hallucinatory experiences, neglect of food, increasing difficulty in conforming to ward routines, verbal expressions which seemed to indicate increasing discomfort with a marked increase in psychotic content, the drug free interval was terminated.

In this phase of our study, the MSRPP ratings (Table 1) tended to show a range of variability which indicated that its application to such a small sample was limited. Obviously a larger number of patients would have to be studied through a series of drug free and treatment phases.

Table 2 indicates that the drug free interval ranged from 3 to 27 weeks. Following this initial drug free phase, different dosage levels were used for varying periods in order to obtain some information as to the levels at which maximum improvement occurred as observed by clinical comparisons of the remission obtained and for the purpose of determining the variability of the metabolites being measured.

CHEMICAL METHODS

The available techniques for measuring the excretion of free chlorpromazine and its sulfoxides in the urine were utilized,

modified, and refined. In addition blood analyses(25) were also carried out from time to time to obtain the levels of chlorpromazine in relation to the dosage used. Comparative paper chromatographic study was carried out on each patient's urine. Studies were initiated to determine the amount and types of chlorpromazine glucuronides(24) present in the urine. These studies will be reported later since this report is concerned only with the excretion of free chlorpromazine and its sulfoxides.

Twenty-four urines were difficult to obtain because of the patient's mental state and various procedures had to be developed for securing specimens at fixed intervals. For a period of time urine specimens from the 7 patients were collected every 2 hours during a 24-hour period on the first day of the week and for the rest of the week at 3-hour intervals during daily 12-hour periods from 10:30 a.m. to 10:30 p.m. (Table 3). The specific gravity of the specimen was recorded and the specimen stored in a refrigerator until analysis could be carried out. At this time 1 ml. each of the sample of each specimen was subjected to the FPN test(23) and spectrophotometric analysis for free chlorpromazine and chlorpromazine sulfoxides (Figure 1).

Later a procedure was utilized in which the 24-hour urine output was estimated by the creatinine content of the day's urine specimen. The standard creatinine excretion rate for each patient was determined in the following manner: 24-hour specimens were obtained by collecting urine every 2 hours for 3 consecutive 24-hour periods for each patient. The creatinine output per day was determined as the mean value for these 3 specimens. The maximum deviation from

the mean for any patient was 10%. This figure was utilized for estimating the total urinary output. This in turn was utilized for calculating the excretion of free chlorpromazine and its sulfoxides for each day. The control run of 24-hour urine output and creatinine determination was repeated at different seasons of the year to account for any seasonal fluctuation of urine output. The creatinine levels were determined in an "autoanalyzer." The average deviation from the mean value ranged from 2.46 to 6.67%.

In the analysis of the urine for chlorpromazine sulfoxide (CP and CPO respectively) a series of preliminary steps had to be taken: the development of a quantitative method for chlorpromazine and chlorpromazine sulfoxide in urine, and the determination and identification of CP and CPO in the urine of patients receiving chlorpromazine.

Method for estimation of total CP and CPO in urine. Various quantities of CP in normal urine were prepared and samples of 1 ml. of the mixture were adjusted to pH 12 and extracted with 12 ml. C_6H_6 . After being centrifuged, the C_6H_6 layer was separated.

To 10 ml. of the C_6H_6 extract, 3 ml. of As_2O_5 (saturated in concentrated HCl) reagent (27) was added. The purple color which developed was read within 10 minutes in a Beckman DU spectrophotometer at 575 $m\mu$. The color density followed Beer's law. The color produced by the As_2O_5 reagent fades slowly on standing at room temperature, but there is less than 2% change in 10 minutes.

Differential method (modified method of Salzman and Brodie(16)). It was found that this method could be refined by carrying it out at pH 12 and utilizing CCl_4 for extracting CP and CPO. When C_6H_6 is used as an extracting solvent, turbidity often developed after shaking the C_6H_6 extract with 50% H_2SO_4 . Another advantage utilizing CCl_4 was that it yielded an extraction of CP and CPO of approximately 96%. Standard curves were made using mixtures of various quantities of CP and CPO in normal urine. A sample of 3 ml. of the mixture was adjusted to pH 12. The mixture was extracted with 12 ml. CCl_4 . After being centrifuged, the urine layer was removed. Ten ml. of the CCl_4 layer were placed in a test tube and

extracted with 2 ml. 0.2M sodium acetate buffer pH 5.6(16) and centrifuged. To 1.5 ml. of the buffer extract (contains CPO) 1.5 ml. of concentrated H_2SO_4 was added with cooling. The pink color which developed was read in a Beckman DU spectrophotometer at 525 $m\mu$. To 8 ml. of the CCl_4 layer (containing free CP) 3 ml. of 50% H_2SO_4 was added, shaken and centrifuged. The resulting light pink color in the acid layer was read as above. The optical density vs. concentrations was plotted on a graph paper. The colors followed Beer's law. The absorption curves of CP and CPO obtained from patients' urines are shown in Figure 2.

the second solvent system, n-butanol-acetic acid-water (4:1:1).

The CCl_4 layer described above contained unchanged chlorpromazine only (R_f , 0.96). Four spots (S_1 — S_4) were found on two-dimensional paper chromatograms of the acetate buffer extract. From the R_f value and mixed chromatograms with authentic specimens, 3 spots were tentatively identified to be chlorpromazine sulfoxide (S_2 , R_{f2} , 0.86), nor₁-chlorpromazine sulfoxide (S_3 , R_{f2} , 0.80) and nor₂-chlorpromazine sulfoxide (S_4 , R_{f2} , 0.75) (Figure 1). The S_1 was very faint and its nature has not yet been identified. All these 4 spots failed to

FIGURE 2
Absorption Curves of CP and CPO in Patients' Urine

Paper Chromatography. It was found that a more sensitive and specific method for the determination of individual metabolites could be performed using paper chromatography. Two-dimensional ascending paper chromatograms were developed on Whatman 3MM paper with the first solvent system, ethanol-n-butanol-water (2:5:5) and

produce color with $FeCl_3$ solution. The R_f values of these 4 compounds did not change after being treated with bacterial β -glucuronidase in a neutral medium at 37° C for 24 hours, and the chromatogram of the hydrolysate did not produce color with ammoniacal $AgNO_3$ reagent. The proportion of S_4 was found to be larger than S_3 and S_2

on the chromatograms. This technique was developed into a quantitative one-dimensional method for the analysis of urinary CP and CPO. Paper chromatograms of 0.3 ml. specimens of mixtures of various quantities of CP and CPO in normal urine were developed with the solvent system ethanol-n-butanol-water (2:5:5) by ascending technique. The chromatograms were dried and sprayed with 50% H_2SO_4 to develop color. Approximately one inch squares including the spots of CP and CPO were cut out, extracted with 3.5 ml. of 50% H_2SO_4 and filtered. The acid extracts thus obtained were read in Bausch and Lomb "spectronic 20" at 525 $m\mu$. The details of the quantitative paper chromatographic analysis of the urinary chlorpromazine metabolites will be reported later (26).

The sensitivity of the techniques utilized for identifying CP and CPO by using the As_2O_5 reagent, the modified method of Salzman and Brodie and the quantitative paper chromatography (Table 3, a, b, c) was found to be approximately 3.0/ml., 1.3/ml. and 1.0/ml. respectively. The results of the FPN test (23) agreed fairly well with that of the quantitative determinations during the period of continuous medication.

RESULTS

Table 1 reveals that the patterns of behavior of these 7 patients in their states of regression and remission varied. The patients Nos. 1, 2, 3, and 6 displayed some of the characteristic behavior considered target symptomatology for the phenothiazine tranquilizers, namely, hyperactivity, hyperirritability, aggressiveness and hostility. However, patients Nos. 4, 5, and 7, although they did not display the characteristic target symptomatology, also responded with some improvement to drug therapy. This is also indicated by the MSRPP ratings with only patients Nos. 5 and 6 showing changes which appear significant by inspection.

The drug free interval ranged from 3 to 27 weeks. The constancy of this interval for each patient is being investigated at the present time by exposing the patients to repeated courses of drug therapy followed by drug free intervals, in conjunction with continuing metabolic studies to be reported later.

Table 2 indicates the excretion of chlorpromazine and its sulfoxides at different dosage levels and the relationship of these in the individual patient. It will be noted that 3 different techniques were utilized in making these determinations. In sequence these were: the use of the As_2O_5 reagent, the modified method of Salzman and Brodie, and quantitative paper chromatography. These developments increased the sensitivity to a point where the presence of 1 gamma of the free CP or CPO per ml. of urine could be measured with a maximum error of 15%. It was also reassuring to find that all 3 methods tended to yield approximately the same type of information as indicated in Figure 3.

FIGURE 3

Average Daily Excretion of Chlorpromazine (CP) and Chlorpromazine Sulfoxide (CPO). Numbers Identify the Patients in Table 3

The single daily urine specimen obtained at the period of nearly maximum excretion contained an amount of chlorpromazine ranging from 0.25 to 14.80 mg. The CPO ranged from 3.35 to 188.10 mg. at the dosage levels employed in this study, which range from 300 to 1200 mg. daily. The ratio of CP and CPO was found to vary each day (Figure 4); however, the average ratio of

FIGURE 4

Daily Excretion of CP and CPO, and the Duration of Excretion After the Discontinuation of Oral Medication of 300 mg. t.i.d. in One Patient (No. 1) (Specimens Were Analyzed by the Modified Method of Salzman and Brodie)

these 2 metabolites was found to be approximately 1 to 16.

It would thus appear that in approximately 3,600 urine specimens tested from the 7 patients under continuous medication, the excretion of CP was very low, usually less than 1% of the administered dose which is in agreement with other reports(14, 16). The rate of excretion of CPO was found to be between 1 to 18% of the administered dose. It would also appear that the excretion of CP and CPO is not proportional to the dosage.

The urines of patients Nos. 1 and 2 were collected at fixed intervals during the day to determine the period of maximum excretion (Table 3). It will be noted that the highest total excretion of chlorpromazine

was found in the third specimen (4:30 p.m.) collected a half hour after the third dose.

As will be reported in detail later, it was found that the major portion of the metabolites being excreted was in the form of glucuronides(24) which disagrees with the results of Berti and Cima(14) who reported that 90% of the metabolites consisted of sulf-oxides in man.

No attempt is made to present the data on the excretion of the metabolites following the termination of drug therapy since this is still under study and is being repeated through a series of drug free phases. In a preliminary study, as indicated in Figure 4, the urinary excretion of CP and CPO continued for an average of 4 to 5 days after the

discontinuation of the medication while the other metabolites could be detected for 7 to 8 days. Much longer duration of excretion of CP (7 days), CPO (3 weeks) and the glucuronides (2 months) was observed in one patient in quantitative paper chromatography (26).

DISCUSSION

The first goal of this study had been the determination of the total amount of free chlorpromazine and its sulfoxides in the urine of chronically ill, psychotic patients being maintained on chlorpromazine. The results have indicated that this is a relatively minor pathway for the excretion of the chlorpromazine metabolites. The hydroxy derivatives and the glucuronides remain to be accounted for. From data already available to us, glucuronide formation (24) represents a relatively major pathway of chlorpromazine metabolism (24).

The question which naturally follows is: Are the metabolites in any way therapeutically effective in themselves? Data now available indicate that the sulfoxides have little effect pharmacologically (16) and there is reason to suspect that the glucuronides are even less effective.

The significance of the persistence of excretion of free chlorpromazine and its sulfoxides in the urine of patients when medication is discontinued and whether differences in this excretory pattern have any correlation with the duration of the clinical remission is under study. From the very preliminary information now available no definite trend or direction can be noted. The pattern of chlorpromazine metabolites excreted in the urine is being studied during repeated phases of on and off medication.

Whether these patients will behave consistently during the drug-free periods is also under study particularly in relation to personality structure and environmental happenings. Despite these considerations the variables relating to the metabolic process must be clearly defined before these other issues can be dealt with more definitively. The difficulties in correlating psychometric studies such as the MSRPP with clinical changes and the determination of end points emphasize the fact that there are no objective criteria for psychiatric alterations ex-

cept of the most marked type. Whether end points can be determined more effectively and at earlier periods and whether a study of the metabolites may provide further clues for the management of dosage will require long term studies with a group of carefully observed and sufficiently cooperative patients. A start has now been made in this direction.

SUMMARY

A group of 7 chronically ill, male, schizophrenic patients living on the same ward over a period of at least a year were studied. Spectrophotometric measurements of approximately 3,600 urine specimens were performed in order to determine the excretion pattern of free chlorpromazine and the 3 chlorpromazine sulfoxides which were identified on paper chromatograms.

The average excretion of free chlorpromazine and its sulfoxides combined during the period of continuous medication with chlorpromazine at dosage of 100 mg. to 400 mg. t.i.d. ranged from 1.31 to 20.54% of the administered dose. Of this, free chlorpromazine was usually found to be less than 1%, while the sulfoxides ranged from 1 to 18% of the administered dose. The average ratio of free chlorpromazine to its sulfoxides was found to be approximately 1 to 16. After the medication was stopped, free chlorpromazine and its sulfoxides disappeared from the urine within 5 days.

A FURTHER STUDY OF SOME FEATURES OF THE INTERVIEW WITH THE INTERACTION CHRONOGRAPH

VICENTE B. TUASON, M.D., SAMUEL B. GUZE, M.D.,
JAMES McCLURE, M.D., AND JERRY BEGUELIN, A.B.^{1, 2}

The search for adequate methods of objectively assessing changes in behavior is an old problem among psychological investigators. The use of the interview as an instrument of assessment has been lauded because of its obvious flexibility and uniqueness. It has also been severely criticized because of its frequent unreliability. The corollary difficulty of finding a suitably precise instrument to record clinical interviews has also posed a challenge for researchers in the field. The development, by Chapple, of the interaction chronograph(1) and his introduction of the standardized interview(2) suggested a way for some answers to these problems. The basis of Chapple's interaction method is an analysis of the time variable during the interview. After considerable work in this field, Chapple arrived at his conclusion that time was an important variable for describing human relations. He suggested that: "... if we want to predict how people will act, the way to do it is to watch how they do act and not to infer their behavior from what they say without any means of observational check." He further emphasized that personality can be assessed without recourse to intra-psychic and other psychodynamic formulations, and that this assessment involves merely the process of observing the time relations in the interaction patterns of individuals. He indicated that this method, because of its objectivity, can lead to a science of personality. This view is consistent with MacKinnon's conclusion that the most promising approach to personality assessment will come from a "field theory" which gives sufficient weight both to "organismic" factors (the individual's behavior) and the "situational" or "field"

(which involves the other interactees) variable(5). It is significant to note that Sarason (and others) have attempted to view the Rorschach Test in a similar manner and have emphasized the examiner-subject relationship and the effects of this on the subject's productions(11).

There have been a series of reports dealing with the interaction chronograph. A history of the development of various early forms of this instrument will be found in the paper by Chapple(1). Essentially the interaction chronograph, which records certain temporal aspects of verbal and gestural interactions, is nothing more than a very elaborate stop watch. The device allows the observer to record, in time units with a high degree of precision, the behavioral interaction (exclusive of content of the verbalizations) of two individuals. The variables, definitions of which are given in Table 1,

TABLE 1
Definitions of the Interaction Variables

1. *Pt.'s Units*: The number of times the patient acted.
2. *Pt.'s Action+*: The average duration of the patient's actions.
3. *Pt.'s Silence+*: The average duration of the patient's silences.
4. *Pt.'s Tempo+*: The average duration of each action plus its following inaction as a single measure.
5. *Pt.'s Activity+*: The average duration of each action minus its following inaction, as a single measure.
6. *Pt.'s Adjustment+*: The durations of the patient's interruptions minus the durations of his failures to respond, divided by Pt.'s Units.
7. *Interviewer's Adjustment+*: The durations of the interviewer's interruptions minus the durations of his failures to respond, divided by Pt.'s Units.
8. *Pt.'s Initiative*: The percent of times, out of the available number of opportunities (usually 12) in Period 2, in which the patient acted again (within a 15-sec. limit) following his own last action.
9. *Pt.'s Dominance*: The number of times

¹ From the Department of Psychiatry and Neurology, Washington University School of Medicine, St. Louis, Mo.

² Work done during the tenure of a U.S.P.H.S. Student Research Scholarship.

This investigation was supported by a research grant (My-2242) from the Institute of Mental Health, Public Health Service.

(out of 12) in Period 4 that the patient "talked down" the interviewer minus the number of times the interviewer "talked down" the patient, divided by the number of Pt.'s Units in the Period.

10. *Pt.'s Synchronization*: The number of times the patient either interrupted or failed to respond to the interviewer, divided by the number of Pt.'s Units.

11. *Interviewer's Units*: The number of times the interviewer acted.

12. *Pt.'s Quickness*⁺: The average length of time in Period 2 that the patient waited before taking the initiative following his own last action.

13. *No. of Interruptions*: The number of times one interectee interrupted the other during the total interview (or a period thereof).

14. *Length of Interview*: The duration of the interview in min.

⁺ Values for these variables are recorded in hundredths of a min. To convert to sec. multiply the given value by 0.6.

are objectively recorded by an observer who activates a series of electrically controlled counters which are connected to two keys, one for the interviewer, the other for the subject. Each key is depressed by the observer whenever the designated individual is talking, nodding, gesturing, or in other ways communicating (interacting) with the second person. Values for these variables can be abstracted from the printed record of the total interview with little difficulty. Some of these variables may seem unusually arbitrary, since they represent algebraic sums of two variables rather than individual measures of each of these variables. Chapple, in developing his interaction theory of personality, considered these derived variables more useful than the first-order variables from which they were obtained. In

addition to containing individual counters for each variable, the interaction chronograph has a "signal" counter which, when pressed by the observer after a pre-arranged signal from the interviewer, functions as a marker to record the start of different periods of the interview.

In his early study of interaction patterns during interviews, Chapple placed little restriction upon the interviewer other than that he should use a non-directive interview of the type described by Rogers(10). He soon discovered, however, that every interviewer was different not only in the way he behaved but in the results that he obtained from the same subject. Evidence for this very important point is provided in several reliability studies done by Chapple (2), and by Goldman-Eisler working independently in England(3).

They found that the use of the interaction chronograph for the objective assessment of patient personality patterns is made more difficult by the differences in "interaction patterns" (or "personalities") of different interviewers. These studies have shown that the differences in inter- and intra- interviewer interaction patterns have a subtle but marked effect on the interviewee's interaction patterns when these are carefully and objectively recorded. These experimental results thus have helped to define some of the uncontrolled variance which in the past has made the interview, including the interviewer's behavior, unreliable.

The need for some control or standardization of the interviewer's behavior if the clinical interview is to be used as a research tool is obvious. Accordingly Chapple suggested some rules to guide the interviewer's

TABLE 2
Characteristics of the Standardized Interview

PERIOD	TYPE OF INTERVIEWING	DURATION OF PERIOD	
		FIXED DURATION	VARIABLE DURATION
I	Free	10 Min.	12 failures to respond, or 15 min. whichever is shorter
II	Stress (silence)		
III	Free	5 Min.	12 interruptions, or 15 min., whichever is shorter
IV	Stress (interruption)		
V	Free	5 Min.	
Total		20 Min. plus	a maximum of 30 more min.

behavior(2). In addition, by prescribing that the interviewer behave in a number of different specified ways as the interview proceeds, it was possible to sample a larger portion of the interviewee's repertoire of responses. The standardized interview is divided into 5 periods. The characteristics of the standardized interview are shown in Table 2 and the "rules" governing the interviewer's behavior are given in Table 3.

TABLE 3
Standardized Interviewer's Behavior :
Rules for Interviewer

Periods 1 to 5 (all periods)

a. Interviewer introduces each period by a 5-sec. utterance (following his signal to the observer).

b. All interviewing must be non-directive. No direct questioning, no probing or depth interviewing. Interviewer can reflect, ask for clarification, ask for more information, introduce a new topic area, etc. In general, interviewer's comments should be non-challenging and open-ended and related to the patient's past comments or to some new, general topic.

c. All interactions must be verbal only, or verbal and gestural at the same time; i.e., interviewer cannot use head nods and other gestures alone. This rule simplifies the observer's task.

d. All of interviewer's utterances must be of approximately 5 sec. duration.

e. After patient finishes a comment or other interaction, interviewer must respond in less than 1 sec., except as otherwise noted in Periods 2 and 4.

f. Each time patient interrupts interviewer, the latter must continue to talk for 2 more sec. This rule insures more explicit definition of a patient's ascendance-submission pattern than would be possible if interviewer "submitted" immediately.

g. After interviewer has been silent for 15 sec. (and patient has not taken initiative) interviewer makes another 5-sec. comment.

Periods 1, 3, and 5

a. Interviewer must never interrupt patient.

b. If after interviewer makes a comment patient does not respond, interviewer must wait 15 sec. and then speak again for 5 sec.

Period 2 only

a. Interviewer must "fail to respond" to last interaction of patient a total of 12 times (or period 2 should last for 15 min., whichever is shorter.)

Period 4 only

a. Each time patient acts, interviewer must

interrupt patient for 5 sec. for a total of 12 times.

b. Interviewer's interruption should begin about 3 sec. after patient has begun his interaction.

c. After having interrupted patient, if the patient continues through the interruption (does not submit), interviewer will not interrupt again until patient has finished his utterance, i.e., interviewer will interrupt patient only once during each utterance of the latter if patient does not "yield."

d. The period is ended after 12 interruptions or 15 min. of attempting to obtain these.

A number of reliability studies have been published dealing with several aspects of the standardized interview.

OBSERVER RELIABILITY

A study reported by Phillips, *et al.*(9) utilized one highly experienced observer and another observer with only minimal experience. They independently and simultaneously observed the same 17 interviews. From their results it is clear that the observation and recording patterns during the standardized interview are highly reliable. The findings in this study served to indicate that the observer's task is largely a mechanical one once he has read, understood, and practiced the published rules.

SCORER RELIABILITY

The interaction chronograph yields cumulative scores on the several variables, and thus scoring, which involves primarily simple arithmetic skills, is a reasonably objective procedure. Saslow, Matarazzo and Guze(14) reported the scores of 2 scorers who followed Chapple's manual of instructions. They scored independently the interaction chronograph records of 10 standardized interviews selected at random. The results indicated perfect agreement between the 2 scorers on 96% of the 600 individual final scores involved. The magnitudes of the errors involved in the remaining 4% were very minimal and they were of the order of 1 unit in whole number scores and .06 in those variables measured in hundredths of a minute. Thus it would appear that scorer reliability presents no problem in these observations.

INTERVIEWER RELIABILITY

Because of the nature of the standardized interview itself, interviewer and interviewee performance are mutually dependent and thus the question of the reliability of the interviewer's standardized performance (the independent variable) is confounded with that of the interviewee's performance (the dependent variable). Thus the patient, free to manifest his individuality, sets the pattern both for content and temporal characteristics, while the interviewer must follow him, imposing only the predefined constraints set forth in Tables 2 and 3. Saslow and Matarazzo(12) however made indirect approaches in assessing the reliability of each participant. Their statistical data gave evidence that the interviewer is able both to learn and to follow the rules of the standardized interview to a reasonably high degree.

INTERVIEWEE RELIABILITY

There are 3 published studies concerning this aspect of the method. The first study (14) revealed that the interviewee interaction variables for any given subject are quite stable across 2 different interviewers, when the latter standardized their interviewing behavior (without standardizing the content of their interviews). At the same time, it was demonstrated that the variables are modifiable by planned changes in the intra-interview behavior of each interviewer. A second study(6) replicated the general stability and specific modifiability of interviewee interaction patterns which were found in the first sample of subjects. The second study used a different series of subjects. In a third study(13), the stability and modifiability were again shown when only a single interviewer was used and the test-retest interval was extended to 7 days. The first 2 studies employed a test-retest interval of a few minutes.

With the demonstration of observer, scorer, interviewer and interviewee reliabilities, we turned our attention to the question of the validity of some facets of the interview technique. It has been noted earlier that all the studies described previously were based upon the use of the standardized interview. This contains several sub-periods during which the interviewer's behavior varies in accordance with certain rules

(Table 3). This is in order to control for the known effect on the subject's interaction chronograph responses if the interviewer's behavior varies, as pointed out previously by Goldman-Eisler(3). Since the standardized interview involves complex behavior patterns on the part of the interviewer, the present study concerned itself with the more simple sub-period of the interview. In this study, we limited ourselves to interviews using the behavior of the "free" period, or the Period I type of interviewing. In this period, the interviewer tries to make his utterances as non-directive as possible, approximately 5 sec. long each time, without either interrupting the subject or delaying his response more than half a second.

On the basis of his experience, Chapple selected a duration of 10 min. under baseline condition as representative of a subject's behavior during a nonstressful interaction (Period I). Guze and Menseh(4) studied this question further. Their findings with 19 subjects suggested that the variation within any single 30-min. interview between successive 10-min. intervals of Period I type behavior might be too great to justify selecting 10 min. as a baseline for comparison with other intervals.

We decided to repeat this study with a larger group of subjects and to further evaluate the reliability of a 30-min. Period I type interview using one interviewer, and a 7-day test-retest interval. Ultimately our research plan involves the assessment of the changes in interaction patterns following the administration of controlled doses of drugs. A reliable baseline measure is therefore of utmost importance for this purpose.

METHOD

The present study was initiated after 3 experienced interviewers and an observer practiced the interview technique and observing respectively. The research design called for interviewing 50 white patients randomly selected from the Washington University psychiatry clinic. They were all new patients in the clinic or had not been seen for at least a year. There were 30 males and 20 females, ranging in age from 17 to 72. The presenting problems were typical of the outpatient clinic population. Diagnostically, there were 13 cases of anxiety neurosis,

acute and chronic ; 8 cases of hysteria (conversion reaction) ; 10 cases of depression of the manic-depressive variety ; 4 cases of schizophrenia ; 10 cases of personality disturbances ; 2 cases of chronic brain syndrome ; 1 case of chronic alcoholism ; 1 case of drug addiction ; and 1 case without any obvious clinical psychiatric difficulty.

The interviews were conducted on one side of a one-way vision screen with the observer on the other side to activate the apparatus. Each patient was subjected to a 30-min. interview of Period I type behavior (Table 2). Each patient returned a week later for a similar interview.

Nearly all the previous work dealing with the interaction chronograph in the study of interview interaction has depended upon the use of equipment rented from the E. D. Chapple Co. One of the major advantages to using Chapple's machine is the fact that many of the calculations based upon the basic, observational data are handled automatically and cumulatively. Since we were not interested, however, presently in many of Chapple's second order variables which were based upon various combinations of the basic elements of the interaction, we worked out a satisfactory alternative to Chapple's apparatus.

After experimenting with different kinds of recorders, we selected a 5-channel Esterline-Angus. It uses standardized paper in relatively inexpensive rolls which come ruled in various time intervals. By selecting an appropriate gear ratio, we can run the recorder so that the paper is moved at 3" per min. Using paper No. 1705-C, we found that this provides ruled lines at 2-sec. intervals with heavier lines at 10-sec. intervals and still heavier lines at 60-sec. intervals. These lines are 1/10", 1/2" and 3" apart respectively. The ink line can be read to the nearest second. The record, using this apparatus, consists of 3 continuous synchronous parallel ink tracks, one for the patient, one for the interviewer and a signal track. The appropriate pen is deflected about 1/10" whenever the corresponding key on a small key-box is depressed by the observer to indicate that the designated individual is interacting during the interview. At the conclusion of the interview, the relevant chronograph variables are extracted from

the record : the number of times the patient interacts (units), the duration of the interaction (action) and the duration of the silence (silence).

STATISTICAL ANALYSIS

Both Spearman rank correlation coefficient (ρ) and Pearson product moment correlation coefficients (r) were used. Previous studies (6, 13, 14) suggested that ρ is the more appropriate statistic for this type of data in view of the concomitant problems of extremely narrow ranges, limited frequencies, and some occasional asymmetrical distribution of the scores. Values for r are thus included in the tables only for purposes of comparison.

RESULTS AND DISCUSSION

The total number of units, mean action, and mean silence and their standard deviations are presented for each subject for both interviews in Table 4. The units ranged from 1 to 69 in the first interview, and 1 to 81 in the second interview. The mean actions ranges from 11 sec. to 1800 sec. (or 30 min.) in the first interview, and 17 sec. to 1800 sec. in the second interview. The mean silences ranged from 4.6 sec. to 12.1 sec. in the first interview, and 4.9 sec. to 10.1 sec. in the second interview. There are no standard deviations for the following : the mean silence period of the second interview for subject 14 ; the mean action period of the second interview, and the mean silence period of the first and second interview for subject 36 ; the mean silence period of the second interview for subject 44 ; and the mean action period and mean silence periods of the first and second interview for subject 47. This is because these subjects interacted or were silent only once.

As mentioned earlier, this study confined itself to consideration of only a part of the standardized interview. A major part of the statistical testing therefore was confined to the analysis of the "action" scores. The "silence" variable was not subjected to detailed analysis because inspection revealed a very limited range in the scores for this variable, making statistical analysis of little usefulness. The reason for this can be attributed to the character of the interview itself. In all cases, the maximum time an

interviewee can possibly be silent is 15 sec. (Table 3). It is therefore apparent that variations in the silence score are not likely to be striking.

According to the "rules" of the standardized interview (Table 3) no restrictions are placed on the length of the "action" period (the duration a patient talks). The subjects could vary in their behavior in this Period I type of interviewing so that the length of this period could range from, say, 1 sec. to 1800 sec.—the full 30 min. We arbitrarily assigned the duration of 1800 sec. to subjects that interacted once for the whole period. Such is the case in the second interview with subject 36 and in the first and second interview with subject 47. Analysis of the data in Table 4 will show that the scores are of an asymmetrical distribution. The distribution is graphically represented in the accompanying histogram (Graph 1).

The rank order correlations (ρ) and the Pearson correlation coefficients (r) for mean actions are shown in Table 5. $A_1-A_2-A_3-A_{1,2}-A_{1,2,3}$ represent mean actions in the first 10 min., second 10 min., third 10 min., first 20 min. and entire 30 min. respec-

tively of the first interview. $B_1-B_2-B_3-B_{1,2}-B_{1,2,3}$ represent the same parts of the second interview. It will be noted that N is not 50 in each case. This is because in some patients, it was not possible to divide the full interviews into 10-min. sections since the subjects continued to talk beyond the 10-min. point.

Examination of the data in Table 5 shows the striking stability in the action variable from one interview to another conducted a week later. The correlations between the whole 30-min. interviews and the correlations between the successive 10-min. periods within a single interview are all highly significant. These results agree with the hypothesis that patients unfold their behavior during the course of a 30-min. interview in a way that is reliable from interview to interview, and that the behavior early in a given interview is very much like the behavior later in the same interview. The findings revealing the stability of the 10-min. period in this study is in contrast to an earlier observation previously noted (4). A re-analysis of the data (mean actions) in the previous study, however, revealed some significant points. Their data were found also

to follow a skewed distribution. A rank order correlation, a more appropriate statistic than the Pearson r which was used, for the 10-min. periods in the other study showed values of .700, .722 and .839 for Periods 1 and 2, 1 and 3, and 2 and 3, respectively. These are all significant at the .01 level of confidence and compare favorably with our findings.

Reading across the rank order correlations in Table 5, one is struck by the consistently lower correlations obtained in comparing the successive 10-min. periods of the first interview with the correlations obtained between successive 10-min. periods

in the second interview. The reason for this difference is not apparent at present. That this is a function of true patient-stability as a result of interacting with the same examiner a second time is suggested as a tentative hypothesis. Our data do not provide the answer. Finally a word should be mentioned about the high value of the correlation coefficient obtained for the total interview. The rho of .903 for the full 30 min. is seen as the highest value obtained. This finding naturally suggests that the reliability increases proportionately as the number of observations increases.

Table 6 shows the data in 3 reliability

studies reported previously. The results of the present study are given for comparison. The marked concordance of our findings with previous works is quite striking. The findings of much less variability (or more stability) of the 3 variables (units, actions, silences) in our series can be accounted for by several factors: firstly, our investigation dealt with a much larger sample (50 vs. 20); secondly, we utilized only the simple part of the standardized interview; and lastly, we extended the observation from 10 to 30 min.

SUMMARY

A brief review of the concepts and methods involved in the objective description and measurement of "personality" by means of interaction chronograph methods, together with a comment on previous studies, have been presented.

The present study was concerned with testing the reliability of 10-min. and 30-min. samples of Period I type behavior, following the rules of a partially standardized interview. Using interaction chronograph measures, it was concluded that 10 min. are sufficient to reach a stable pattern of patient communication under Period I conditions. It was established further that extending the period of observation to 30 min. offers a much more stabilized interaction.

TREATMENT METHODS AND FASHIONS IN TREATMENT

LEONARD CAMMER, M.D.¹

It seems that in the current practice of psychiatry, the fashion for almost every kind of nervous and mental disorder is pharmacotherapy. There are "psychotropic" and "neuroleptic" tranquilizers, energizers (can brain function be "energized"?), antidepressants, hallucinogenic chemicals, and other drugs, all representing the latest in psychiatric treatment.

But while the chemists produce more rings and side chains to the already existing compounds, perhaps we should take a second look at the impact of this new wave of pharmacological therapy on clinical practice. Fashions in medicine, as in clothes and cars, can lead too readily to a discard of the usable and useful. Proven therapeutic methods may be brushed aside for the sake of boarding the bandwagon. With such easy acceptance of newer agents no time is taken to evaluate their worth. This illusion of progress can be damaging as dubious rationalizations (needed to reinforce the illusion), often cover up failures in clinical judgment and integrity.

Psychiatrists today are pounded by impressive reprints of scientific articles, extravagant brochures, and eloquent detail men offering samples and promoting the therapeutic merits of various pharmacological products. For example, it is claimed that a certain antidepressant drug will "eliminate" or "reduce" the need for electroshock treatment (ECT), or serve as a useful alternative. The sales literature is replete with implications that ECT is to be avoided, that it is old-fashioned, and that it is almost contraindicated when compared to an available drug which can be prescribed in a convenient dosage regimen. Such an appeal (especially if the psychiatrist or other physician is not geared to administer ECT personally), is of course, very persuasive. Just have the patient take the pill and await the desired results.

A brochure on one of the very newest antidepressants states that of a certain number of psychotic patients suffering from in-

voluntional melancholia who received this drug, 27% showed marked improvement and 35% moderate improvement. In manic-depressive disease, 34% showed marked improvement and 31% moderate improvement.

But suppose we look at it from the point of view of the patient's need and consider the therapeutic goals required for him. First, we compare the results reported in the brochure with our own intimate knowledge of ECT. In this writer's 15 years of personal experience with ECT, 75% of patients with involuntional melancholia were markedly improved with an average of 9 treatments given in a 3 week period. Such results are confirmed by the work of innumerable clinics throughout the world and Arthur P. Noyes² states: "In the depressions of involuntional melancholia and of manic-depressive psychosis the improvement following ECT is striking. In 80% or more of these disorders five to ten treatments are followed by full or social recovery." Why then, with almost three times the desired results should we discard this treatment? *Must* we be fashionable?

Moreover, there are other and subtler considerations such as the duration of the patient's illness, the degree of suffering, the economic loss to the patient and, particularly in the depressions, the danger of suicide. A fairly common experience where the patient served as her own control can be cited:

A 48-year-old housewife who suffered from repeated manic-depressive, depressed episodes had her first significant depression in 1944. She was ill for 6 months before being treated but recovered after 12 ECT's with a full remission. The second severe depression in 1957 was treated for 4 months with antidepressant drugs and psychotherapy. The patient showed no improvement, finally requiring 14 ECT's for her recovery from that episode. With the onset of the third significant depression in 1961 the patient's husband brought her for treatment after 2 weeks of illness (anorexia, insomnia,

² Noyes, Arthur P.; *Modern Clinical Psychiatry*. 4th Ed. Philadelphia: W. B. Saunders Co., 1953.

¹ 45 E. 85th St., New York 28, N. Y.

tearfulness, self-depreciation, and suicidal pre-occupation). ECT was given immediately. This time the illness required only 8 treatments in an 18 day period for a full remission (although the patient was relieved of "mental pain" and suicidal thoughts after the 4th treatment in an 8 day period).

Early institution of treatment with a proven procedure aborted the illness in less than 3 weeks; the very similar episode 4 years previously, treated first with drugs, required nearly 6 months of therapy (and suffering) and almost twice the amount of ECT because of the delay in administering such therapy.

In dealing with those patients where pharmacological agents have failed to help the condition, this writer has noted that drugs, in too many instances, have deepened the depression, made it refractory to ECT (or at best, created the need for more ECT than previously required), or have helped to convert acute but relatively manageable depressions, into chronic states with poorer prognoses.

Pharmacotherapy is of course proving an enormous benefit to psychiatry and is undoubtedly an addendum to the therapeutic armamentarium. Many patients react to drugs when the illness has not responded to other methods and in numerous cases the drugs are of great value both primarily and adjunctively in the management of a psychiatric patient. Such drugs have also opened many new doors to the mysteries of brain metabolism, neurochemistry and neu-

rophysiology. But why abandon our great store of knowledge which has been so carefully accumulated simply because a new multicolored package wrapped in plastic is handier? It seems as if the clinician who waits for the "follow up reports" and is not content with the large print and graphic displays of the "most recent developments" is in the minority—and old-fashioned.

In clinical practice, the primary goal in therapy is to return the patient to an optimum functioning level in accordance with his potentialities and abilities, and to keep him at this level. Having diagnosed the nature of the disease process, the psychiatrist, rather than reach for the latest sample of a drug in his desk drawer, will structure a comprehensive program, using all forms of treatment available for maximal improvement.

The advent of new treatment measures is always exciting. It creates fresh approaches to research, to studies in etiology and pathology and of course, to diagnosis and treatment. But clinically, the criterion is not newness; it is effectiveness and therapeutic results. Thus, all psychiatrists and other physicians have an obligation to the patient not to discard the useful for the latest, while the younger physicians, particularly those about to go into practice, might do well to familiarize themselves with the "old-fashioned" as well as the new. Fashions do change rapidly in our current age of technology but the responsibility to heal the sick is as old as medicine and this does not change.

CLINICAL NOTES

(The Clinical Notes report the findings of the authors and do not necessarily represent the opinions of the Journal.)

SODIUM AND POTASSIUM CONTENT OF CEREBROSPINAL FLUID COLLECTED FROM PATIENTS WITH CHRONIC SCHIZOPHRENIC REACTIONS¹

TURGUT ZILELI, M.D., LORING FO CHAPMAN, Ph.D.,
AND HAROLD G. WOLFF, M.D.²

During the course of studies(1, 2) primarily concerned with other biochemical properties of cerebrospinal fluid (CSF) collected from patients with schizophrenic reactions, the opportunity was taken to determine potassium and sodium content as well. Although previous studies by others(3, 4, 5) failed to indicate that sodium or potassium occur in abnormal amounts in CSF collected from such psychotic patients, the paucity of data encouraged the assay of these substances in the relatively large number of specimens available.

CSF was collected by lumbar tap from 92 hospitalized patients with a diagnosis of chronic schizophrenic reaction. None was in a highly excited state at the time of study and none exhibited catatonic stupor. Many of the patients were receiving phenothiazine derivatives at the time of study. Sodium and potassium were determined

by flame photometry(6), using a Baird-Atomic flame photometer, model KY 1.

The results of these determinations (see Table 1) indicated that the content of potassium and sodium in cerebrospinal fluid collected from patients with schizophrenic reactions is not different from the content of these substances in CSF collected from patients without significant disease (see Table 2). Further, among the schizophrenic patients, no significant differences in CSF potassium or sodium content were observed when the patients were separated into the diagnostic subcategories of catatonic, paranoid, hebephrenic, or undifferentiated schizophrenia.

PAIRED EPISODES OF MANIC-DEPRESSIVE ILLNESS
WITHIN A SINGLE FAMILY

GEORGE E. VAILLANT, M.D.¹

Jacobs and Mesnikoff(1) reported 4 pairs of twins who demonstrated "alternating psychoses." Although 3 of their twin pairs were identical, the authors suggested psychological factors were responsible for the reported paring of illnesses. Since no study of identical twins can ignore hereditary factors, their thesis can be criticized for failing to discuss this aspect. One might expect identical twins to become ill at the same time. A recent paper by Rosenthal(2) demonstrates how misleading disregard for genetic factors can be, and sharply criticizes the concept that predominantly psychological factors lead to the pairing of schizophrenic illnesses in twins.

This report casts no new light upon genetics but does lend support to the idea that simultaneous onset of psychosis in relatives would appear to have variables other than heredity. The report concerns a family that exhibits a high incidence of manic-depressive psychosis, but whose members, although of different ages, appeared to become ill and to be hospitalized in relation to one another (Figure 1).

The A. family had depressive illness in at least half of the members in direct con-

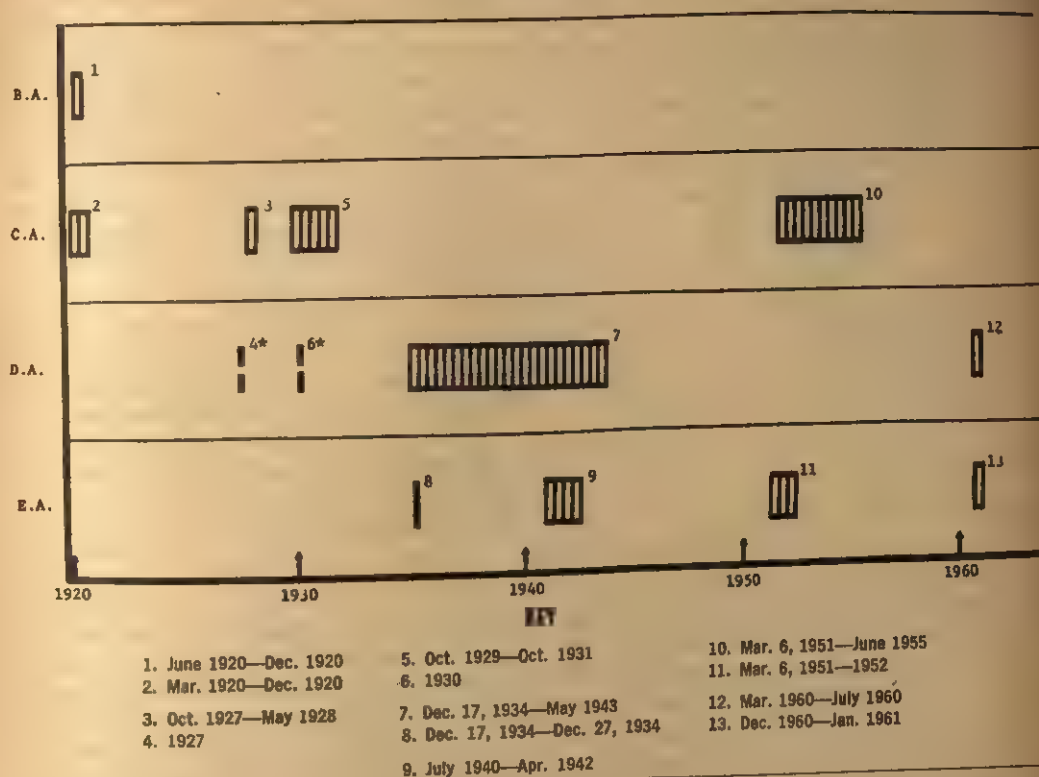

sanguinity to the trio of siblings under study. A grandfather, a maternal aunt, a paternal uncle were all definitely hospitalized; and both parents were alleged to be clinically depressed. Although in the case of 2 of the siblings the diagnosis was initially dementia praecox, retrospective examination of the records reveals that the recorded clinical pictures were equally compatible with manic-depressive illness, and in time the latter diagnosis became clear. The patients recovered from each episode without benefit of somatic treatment or of extensive psychotherapy, and recovered without social deficit, flattened affect, or loosened associations.

The A. family were very close. The 3 children were orphaned in 1910 and lived in a small New England town with their 2 aunts and an uncle. For almost all of their lives they have remained within a few miles of one another, whenever practical have visited each other once a week, and for more than 50 years have been perhaps the most important objects in each others' lives. Only one of the children, D.A., married.

In 1900 at the birth of C.A., the foster mother and aunt of the 3 children had a depression. In 1920 this aunt, B.A., was first hospitalized 3 months after C.A. became ill with an acute psychotic episode. Although

¹ Resident in Psychiatry, Mass. Mental Health Center, and Teaching Fellow in Psychiatry, Harvard Medical School.

FIGURE 1

B.A. was the dutiful, if cold, foster mother when well, she wished to kill C.A. when sick.

Both women made full recoveries, but C.A. had 2 more hospitalizations in 1927 and 1929. On the second admission she finally received the diagnosis "manic-depressive-depressed"; this remained her diagnosis on subsequent admissions. During both her periods of hospitalization, the brother, D.A., experienced bouts of manic behaviour; but although these led to manifestly inappropriate social and business activity, they did not necessitate hospitalization.

On December 17, 1934, the day he was to take his sister, E.A., to the hospital for what was diagnosed as "nervous exhaustion," D.A. became acutely manic and was hospitalized himself for 8 years; except for the manic episodes 5 years earlier, there had been no prodromal symptoms. His mental status varied but was always most consistent with manic-depressive psychosis. His sister was able to return to work after sev-

eral days' hospitalization. Two years later, B.A. died from a cerebrovascular accident; none of the siblings became ill at this time.

In 1940 the youngest sister, E.A., again required hospitalization. She was excited, hallucinating, and her mental content centered around the poor care her brother was receiving in the mental hospital. This was the only illness unlinked by direct temporal association with the onset of illness in another member. The marked affective component of her schizophrenia-like illness led to her diagnosis remaining unclear. After a year she was discharged, "recovered," and held several responsible jobs as did her brother who was discharged a year later.

On March 6, 1951 E.A. took her sister C.A. to the hospital for a severe depression. While the social worker was admitting C.A., E.A. suddenly ceased to be the responsible sibling answering the social worker's questions; she became mute and that afternoon had to be admitted by ambulance to another state hospital. Here, she changed from mute withdrawn behaviour to an acute

manic state, was diagnosed as "manic-depressive—other types," and made a rapid recovery. C.A., on the other hand, although often leaving the hospital on visit, was not discharged for 5 years. Both sisters returned to responsible employment.

In the summer of 1960, following the marriage of his daughter and the loss of his job, D.A. again became agitated and depressed and was hospitalized for 4 months. After he was discharged, his sister, E.A., became increasingly depressed, found work difficult, and finally was dismissed. She was admitted to the hospital somewhat retarded and unable to assume responsibility for her own care. In 2 months she had improved and returned to work.

DISCUSSION

Several facets of this case deserve attention. First, 12 out of 13 psychotic episodes which occurred in 4 individuals over a span of 40 years were paired within a year of each other. The odds are greater than 1 in 10,000 against such coupling occurring by chance. Two pairs of hospitalizations occurred on the same day. Secondly, each member initiated at least one of the paired illnesses; each one except the aunt remained ill for at least a year; and in no case were there shared delusions. This evidence militates against the phenomena of *folie à deux* or psychotic symptomatology

secondary to a conversion reaction.

Finally, although the strong family background suggests a real genetic predisposition, both the striking pairing of the hospitalizations and the excellent social adjustment between illnesses suggest that intrafamilial psychologic factors were crucial in the decompensations. For although extensive psychodynamic evidence is not available, the whole family appeared to exhibit the delicate reciprocal relationships that other studies have ascribed only to twins or mother-child pairs. The same excessive interdependence and covert hostility towards the relative, noted in the study of Jacobs and Mesnikoff, were evident. In 3 cases the particular relative who became ill second had felt directly responsible for the one first hospitalized.

SUMMARY

For one family data are presented to suggest that the specific stress of psychosis in a relative can serve as one of the major precipitating factors in what otherwise might appear to be a largely genetically determined psychosis.

A CLINICAL EVALUATION OF MELLARIL

SOL SHERMAN, M.D.¹

There is little doubt that the phenothiazines have been a boon to the treatment of mental disorders, especially schizophrenic reactions. Following the introduction of the phenothiazine group, there have been attempts to alter the nucleus in an effort to prepare tranquilizers of greater potency, but this has wrought little other than a "battle of the milligrams" comparable to that evidenced earlier with a progression of "new" steroids for the treatment of collagen diseases. While it is true that "more potent"

tranquilizers have been developed, the consequences have not been all salutary, for there has been a noticeable increase in incidence and severity of side effects, especially those related to extrapyramidal stimulation(1).

The value of any therapeutic agent is a composite of clinical efficacy and toleration, and this report is concerned with a phenothiazine that appears to exhibit a high index of usefulness. The chemical configuration of Mellaril² (thioridazine hydrochlor-

¹ Director of Geriatrics, Metropolitan State Hospital, Waltham 54, Mass.

² Sandoz Pharmaceuticals.

ide) is somewhat unique in having a thiomethyl radical in position 2 and a piperidine ring in position 10. A number of clinical studies have shown it to be an effective tranquilizer with little tendency to produce Parkinsonism and devoid of the dystonic reactions encountered with other agents of this class (2, 3, 4).

Mellaril was evaluated over a period of

optimum effect was obtained. A maximum dose of 1600 mg. daily was employed in a few cases, but in general, dosage ranged from 75-600 mg. daily. Special care was taken to titrate dosage to suit the needs of each patient. Each patient was his own control; his response to Mellaril compared with previous medication serving as the yardstick of improvement or lack of it.

20 months in 74 male patients, aged 14-78 (average 42 years) who had been confined to hospital^a for periods ranging from 1 to 31 years (average 8 years). Diagnoses are shown in Table 1 and a breakdown of psychiatric symptomatology in Table 2. In essence, these patients were disorganized and restless, exhibited disturbed thinking and action and were noisy and untidy in their general habits.

This series of patients had previously received various forms of treatment, including most of the presently available tranquilizers, alone or in combination with "energizers," MAO inhibitors and EST and had not responded adequately. The starting dose of Mellaril was 25 mg. t.i.d., maintained for 5-6 days and then gradually increased until

RESULTS

Of the 74 cases, 19 were rated excellent, having improved sufficiently to permit discharge or parole; 16 were considered markedly improved, as measured by significant quietening and tidiness—these were permitted ground privileges and visits to their homes; 15 were rated fair, demonstrating fewer outbursts and moderate improvement. The remaining 24 patients showed no improvement, some through refusal to take medication or discontinuation thereof.

It was interesting to note a change in the ward atmosphere coincident with quietening of the more agitated cases, reduction in disturbances and altercations, better rapport among patients and with nursing personnel. An improved sense of well-being amongst most of the patients was an observation reported by several of the attendants.

The only side effects of any consequence were seen in 2 patients who exhibited pseudoparkinsonism, which occurred near the conclusion of the study and which dissipated following reduction in dosage. Special attention was paid to blood checks(5), with tests being performed before the institution of therapy and once a month thereafter. However, no sign of blood dyscrasia was evidenced throughout this study.

Comparing Mellaril with other therapies that had been employed, it was noted that

the patients receiving it seemed to be alert, in contrast to the "knocked-out" state that had been seen with some phenothiazines. Previous trial with other phenothiazines had been disappointing because of the extrapyramidal symptoms, which appeared with doses too low to afford adequate clinical improvement. It would seem that increased toleration was the major factor in permitting Mellaril to demonstrate its therapeutic potential to a greater extent than that obtained with the other compounds.

SUMMARY

A clinical evaluation of Mellaril in 74 chronic psychotics has shown it to be an effective and well tolerated tranquilizer. Its ability to control or modify major emotional disorders with little or no clouding of consciousness or extrapyramidal stimulation is its greatest *forte* in comparing it with other phenothiazines.

THE USE OF PARNATE IN THE TREATMENT OF DEPRESSION

MILTON H. MILLER, M.D.¹

Management of the depressed patient remains a complex problem for the clinician. Many of these illnesses prove to be very refractory when the criterion of full remission is utilized and a good deal of flexibility and persistence is required on the part of the physician and his patient. The full armamentarium of the clinician, including psychotherapeutic interview, convulsive therapy, outpatient convulsive therapy, the

use of monoamine oxydase inhibitors and other antidepressant medications, particularly Tofranil, may be utilized.

This clinical note will describe work with a promising new antidepressant medication, Parnate.² All patients in this study were treated by this physician in private practice, both in and out of the hospital. Thirty-three patients received Parnate with Stelazine, 1 or 2 mg. in a tablet, Parstelin. The patients

¹ Associate Professor of Psychiatry, University of Wisconsin, Madison, Wis.

² Medication for this study was furnished by Smith Kline & French Laboratories.

were all depressed and most suffered from involutional depressive states. A number of patients had been previously treated with several series of convulsive therapy and a variety of medications, including Stelazine, over the years. Several patients suffered from illnesses which were of schizophrenic nature but with substantial depressive elements. The patients ranged in age from 20 to 70 years.

Results with this medication, administered in dosages averaging 30 mg. of Parnate daily and 3 to 6 mg. of Stelazine daily were generally impressive. Even more impressive was the specific response of several patients who had been in the care of this physician for 5 or 6 years and who had previously failed to obtain substantial or sustaining remission. During one 2-month period, a group of 4 patients were switched from Parnate and Stelazine and were placed on Stelazine and another antidepressant medication. Three of these patients sustained relapses during a 2-month period and thence improved again when placed back on Parnate. Although there were some patients who were totally non-responsive, approximately two-thirds improved moderately to substantially. There were no serious toxic side effects although some patients complained of dryness of the mouth, sweating and some dizziness. The dizziness appeared to be associated with sudden change of bodily position. Another occasionally disturbing side effect was a rather sudden sharp headache which 4 patients reported.

These headaches which were apparently related to the medication and occurred once or twice during the treatment were of brief duration, and not accompanied by any neurologic signs. The headaches were controlled by aspirin.

Routine blood and urine tests and liver function tests were done. No alterations were noted.

The clinical course of these patients was somewhat variable but those who responded well tended to improve during the first 2 weeks and only 2 patients in the group responded well after a period longer than 2 weeks. Following an initial favorable response, the medication was continued, though in smaller doses for periods beyond several months. Some patients have discontinued the medication and have sustained their improvement.

SUMMARY

Six months of clinical experience with a new antidepressant medication, Parnate (tranylcypromine), indicates that this compound is a very effective monoamine oxidase inhibitor. It appears to act fairly rapidly in a wide variety of depressive states and in this examiner's hands seemed to effect remission in several very refractory depressive illnesses. It would appear to be indicated in the treatment of any form of depression and warrants trial in some long depressive illnesses which had been non-responsive to other therapies.

A NON-REPORTED SIDE EFFECT OF IMIPRAMINE

CARLOS A. LEON, M.D.¹

In a group of 50 patients receiving imipramine,² 30 of whom were followed-up for more than 6 months, we found that 5 of the latter presented the following hitherto undescribed reaction:

Around the first or second week of treat-

ment under a daily oral dose of 100-150 mg. of imipramine, an unexpected phenomenon occurred described by the patients as "electric shock," "jerk," "sudden thrill." This happened in all cases when the patients were resting in bed and most often when they were about to fall asleep.

Detailed inquiries about the peculiarities of the above mentioned phenomenon, and the fact that one of the patients who experienced it is a physician, allowed us to

¹ Professor and Chairman, Department of Psychiatry, Universidad del Valle Medical School, Cali, Colombia.

² Supplied as Tofranil through the courtesy of Geigy Laboratories, Basilea.

characterize it as a *single generalized tonic muscular contraction producing hyperextension and lasting for only about a second or less*. No other symptoms were described as preceding, accompanying or following this reaction. Alarm and preoccupation about the symptom were experienced by all patients in moderate-to-intense degrees leading in one case to discontinuance of the medication.

Only one of the patients was receiving additional medication at the time the reaction occurred. None of the patients had ever complained of convulsive disorders in the past. The therapeutic effect in all cases was satisfactory.

Although the symptom occurred usually for several times during the same day, the interval between episodes was never shorter than 2 hours.

We will summarize briefly the case histories :

Case 1. A 38-year-old married male with a diagnosis of manic-depressive reaction, depressive type. Started on 75 mg. a day of imipramine, increased gradually to 150 mg. a day within a week, kept at this dose for 4 weeks, to be gradually reduced to a maintenance dose of 50 mg. a day. On the third week he complained anxiously of having experienced a sensation of "electric shock on the whole body" while falling asleep. This was repeated frequently in the course of the following 3 weeks, appearing at least once a day always when the patient was at rest. Disappeared spontaneously at the end of the sixth week.

Case 2. A 50-year-old widowed female diagnosed as chronic depressive reaction. Imipramine was started at a daily dose of 75 mg. which was increased within 3 days to 125 mg., sustained for a month and then gradually reduced to 50 mg. a day for 2 months. During the first week she experienced "jerks" as if produced by "an electric discharge." The "jerks" continued throughout the fourth week especially when patient was at rest and then disappeared spontaneously.

Case 3. A 60-year-old married male with a diagnosis of involutional reaction. Imipramine was started at a daily dose of 100 mg., increased to 150 at the beginning of the second week, sustained for 2 weeks and then gradually reduced to 50 mg. a day within the following month. During the second week, patient complained of "sudden jerks" or "thrills" generalized to the whole body, which occurred when

he was at rest. These episodes repeated frequently along the second and third week ; patient became quite alarmed about the symptom and discontinued the medication on his own, but was persuaded to restart it the following day at a reduced dose of 100 mg. a day. No symptoms appeared hereafter.

Case 4. A 27-year-old single female diagnosed as schizophrenic reaction, chronic undifferentiated type with superimposed depression. Imipramine was started at a daily dose of 100 mg., increased to 150 mg. on the second week, sustained for 1 month and gradually reduced to 5 mg. within the following month. Eight days after the medication was started, patient experienced a "reaction like an electric discharge" while she was about to fall asleep ; this was repeated several times for 3-4 days while at rest and caused her a great deal of concern but disappeared spontaneously after this short period.

Case 5. A 35-year-old married male with a diagnosis of depressive reaction in an emotionally unstable personality. Imipramine was started at a daily dose of 100 mg., increased to 150 mg. within the first week ; this was sustained for 1 month and then gradually reduced to a daily maintenance dose of 50 mg., within the following month. During all this period, patient kept taking a daily dose of 400 to 1200 mg. of meprobamate, which he started to take 3 months prior to the depressive crisis without ever experiencing undesirable reactions. During the second week, he complained one night of "an instantaneous convulsion" which was repeated on several occasions throughout the fourth week ; he was quite anxious about the symptom and feared that he may develop epilepsy, but it disappeared spontaneously.

DISCUSSION

We have described an undesirable side effect of imipramine which does not seem to be related to individual intolerance, amount of drug or time of administration.

Speculations as to the nature of the phenomenon point to the possibility of a convulsive-like disorder related to cortical or subcortical excitation or to a lowering of the convulsive threshold. The effect seems to wear off spontaneously within a variable period of time.

Epileptic G. M. seizures have been reported in patients treated with M. A. O. inhibitors³ including one case who received imipramine.

³ Sharp, W. L.: Am. J. Psychiat., 117 : 458, Nov. 1960.

The interesting characteristics of the side effect and its apparently high incidence (10% of our cases) make further investigations most desirable.

INDUCED 5-HYDROXY-INDOLE-ACETIC ACIDURIA IN THE SCHIZOPHRENIC AND THE NON-SCHIZOPHRENIC PSYCHIATRIC PATIENT¹

PAUL KOCH, Ph.D., CAMILLE LAURIN, M.D., PIERRE LEFEBVRE, M.D.,
AND PIERRE B. BOURDON, M.D.²

5-hydroxy-indole-acetic acid (5-HIAA) is the urinary endmetabolite of serotonin. Since it has been shown that increasing the brain serotonin will result in hallucinoses (1, 2), an aberration of the serotonin metabolism was hypothesized to be contributory to schizophrenia.

Variations of 5-HIAA are easy to measure. Thus they were a convenient way to demonstrate variations of serotonin metabolism. Several papers deal with differences between schizophrenics and non-schizophrenics in respect to 5-HIAA uria. Feldstein, *et al.* (3) and Buscaino, *et al.* (4) did not find any differences between 5-HIAA uria in normals and schizophrenics. Attempts to induce 5-HIAA uria brought conflicting results. Buscaino, *et al.* (4) find that injected serotonin-creatinine-sulfate shows up as 5-HIAA in schizophrenics at a much higher rate than in normals. Zeller, *et al.* (5) and Lauer, *et al.* (6) report that oral tryptophane will increase 5-HIAA in the normal but not in the schizophrenic. Sachchidanada, *et al.* (7), however, affirm the exact opposite, while Kopin (8) finds increased 5-HIAA in both groups.

No attempt has come to our knowledge to use reserpine as a means to induce 5-HIAA in order to differentiate between the schizophrenic and the non-schizophrenic. Reserpine liberates not only the brain serotonin but the entire body serotonin as well (9, 10).

This paper deals with some experiments to use reserpine induced 5-HIAA uria as well as oral tryptophane as a screening test for schizophrenia.

MATERIALS AND METHODS

Ten male schizophrenics, aged 20-40, suffering from various forms of the disease were compared with a similar group of 12 non-schizophrenic patients. A third group of schizophrenics of various ages, males and females, received only placebos.

On the first day all medication was suspended at noon and was not resumed until after the end of the experiment. The subjects received, however, each evening 200 mg. chloral hydrate to ensure sleep. Fasting was enforced from after supper until noon of the following day. On the second day, the patient was instructed to urinate at 9:00 a.m. and was given a placebo (injection or capsule). All urine was collected for 150 minutes, acidified and put into the frigidaire. On the third day the same routine was followed again. The placebo was replaced by the treatment (an intramuscular injection of 2.5 mg. Serpasil³ or a capsule, containing 100 mg. 1-tryptophane). The nature of the treatment was not known to anyone having any direct contact with the subject.

Because of the profound and lasting effect of reserpine, no inversion of the order of the treatment was attempted. For this reason, the third group of schizophrenics was added. They received placebos on both days. This was done to find out whether variations of 5-HIAA could be due to the withdrawal of the medication.

The urine samples of the second and of the third days were analyzed together for 5-HIAA content according to the method of Udenfried (12, 13) as modified by Garner

¹ This study is supported by the Canadian Ministry of Health and Welfare.

² Albert Prevost Institute, 6555 West Gouin Boulevard, Montreal, Canada.

³ We wish to thank the Ciba Company Limited of Montreal for their gift of Serpasil and the corresponding placebos, as well as Miss Fernande Bastien for her excellent technical assistance.

(14). Creatinine was determined according to standard methods(15).

RESULTS

TABLE 1

	Placebo	Reserpine	Probab. ⁵	Placebo	1-Tryptophane	Probab.
Non-schizophrenic mg. 5-HIAA/ gm. creat.	12.2 ± 2.4	20 ± 2.9	>0.05	11.6 ± 1.6	10.4 ± 1.4	<0.6
Schizophrenic mg. 5-HIAA/ gm. creat.	10.6 ± 1.5	16.2 ± 1.7	>0.05	12.3 ± 2	12.6 ± 2.2	<0.9
	Placebos	1st Day	2nd Day			Probab.
Schizophrenic controls						
mg. 5-HIAA/ gm. creat.		10.6 ± 1.2	9.8 ± 1.1			<0.9

⁴ Standard error of the means.

⁵ The probabilities were calculated by means of Student's "t".

DISCUSSION AND CONCLUSIONS

Reserpine will increase the urinary 5-HIAA excretion of the schizophrenic as well as of the non-schizophrenic control. It was not deemed prudent to repeat the experiments using a higher dosage level of reserpine, as toxic side effects were observed in many of the subjects. A single dose of 100 mg. 1-tryptophane did not vary in any way the 5-HIAA uria of any of the patients nor did the withdrawal of medication.

SUMMARY

Inducing 5-hydroxy-indole-acetic aciduria by injecting reserpine and by oral tryptophane did not differentiate between schizophrenic and non-schizophrenic psychiatric patients within our experimental conditions.

A PILOT STUDY OF L-GLUTAVITE IN HOSPITALIZED "AUTISTIC" AND "HYPERACTIVE" CHILDREN

SEYMOUR LEVEN, M.D., AND ARTHUR S. IMPASTATO, M.D.¹

Recent studies in the use of L-Glutavite on hospitalized elderly schizophrenic patients have indicated that significant improvement may be expected in their mental status and social behavior. With these patients becoming more active and interested in their environment(1, 2, 3, 4), it was felt that a pilot study was indicated to see whether L-Glutavite was of any therapeutic value in "autistic" and/or "hyperactive" children hospitalized at Kings Park State Hospital.

L-Glutavite is a mixture of mono-sodium L-Glutavite plus vitamins and minerals. Upon absorption the L-Glutavite is presumed to appear in the blood as glutamic acid, the main ingredient affecting cerebral metabolism, while the vitamins function in the process as coenzymes.

Thirty-five male children whose ages ranged from 5 to 14 years were selected for the study. Sixteen were "autistic" and 19 were "hyperactive." All were in good physical condition and none was suffering from congenital or organic disease. Complete psychiatric and psychological as well as EEG examinations were performed on each child prior to the study and all forms of therapy and other medication were discontinued.

A simplified behavioristic rating scale was used and each of the children selected was evaluated by 4 different trained observers prior to treatment and bi-weekly thereafter for 6 weeks. Unknown to these observers (ward nurse, school teacher, occupational and recreational therapists) was the fact that only 10 of the "hyperactive" and 8 of the "autistic" children received the L-

Glutavite while the others received the placebo, tomato juice. A standardized dose of one teaspoon of L-Glutavite per 4 ounces of tomato juice was given.

RESULTS

In the group of 10 "hyperactive" children receiving L-Glutavite 2 showed appreciable overall improvement while another 2 only minimal improvement. In the group of 9 "hyperactive" children receiving the placebo 2 showed the same degree of overall improvement and only 1 showed minimal results.

In the group of 8 "autistic" children receiving L-Glutavite none showed any appreciable degree of improvement and only 2 achieved minimal results. Of the 8 "autistic" children receiving the placebo one did improve considerably.

SUMMARY

Of 18 children receiving L-Glutavite in the blind study only 2 showed appreciable improvement in their behavior. Of the 17 children receiving the placebo 3 displayed the same degree of improvement. L-Glutavite in the dose administered during this 6-week study did not cause any marked improvement in "hyperactive" or "autistic" children.

A CLINICAL TRIAL OF CHLORPROTHIXINE

G. G. HAYDU, M.D.,¹ W. BRINITZER, M.D.,² J. GIBBON, M.D.,²
AND L. GOLDSCHMIDT, Ph.D.¹

Chlorprothixine (Taractan)³ is a drug recommended for treatment of a variety of mental disorders. A clinical and toxicological study was undertaken prior to marketing of the drug.

It was planned to give chlorprothixine in dosage up to 100 mg. daily to acutely ill newly admitted patients and in dosage of 200 mg. and over a day to chronically ill patients with symptoms of depression or withdrawal. Experience soon showed that low dosage was not effective, and the drug was then given to acutely ill patients in dosage of 50 mg. t.i.d. for 1 week, 100 mg. t.i.d. for 2 weeks, followed by 150 mg. t.i.d. for 3 weeks. At the end of this period if the patient was unimproved 200 mg. was given t.i.d., and reduced to 100 mg. t.i.d. in event of improvement. Determinations on blood were performed weekly for 3 weeks and then bi-weekly, as follows: total white blood count, differential white blood count, hematocrit, alkaline phosphatase, and non-protein nitrogen. Determinations on urine were made at the same frequency, as follows: specific gravity, albumin, glucose, microscopic studies.

Clinical evaluation was done by super-

vising psychiatrists, according to symptom complexes. Excitement was the most frequently occurring symptom complex including aggression and combativeness. Delusions and hallucinations were next most frequent, then withdrawal and autism, dissociation and motivational confusion, and depression. Table 1 shows the study population by sex, by age decades and by diagnostic designation.

RESULTS

Forty-seven patients (33%) improved, 60 (42%) did not change and 37 (25%) showed worsening of the major symptom complex. The only symptom complex which showed no change was hallucination and delusion. There were only two instances of leukopenia and one instance of increase in alkaline phosphatase. Upon withdrawal of the drug these disappeared after 2 weeks, and their relation to the drug therapy is uncertain. The drug was well tolerated by patients. The most frequent side effects were somnolence and tachycardia. There were no extrapyramidal symptoms, even at high dosage.

Our clinical observations indicate that chlorprothixine is an effective sedative. Its tranquilizing effect is considerably less than that of chlorpromazine, and it did not alter delusions or hallucinations. An antidepressant effect of the drug was not apparent, even at high dosage.

CASE REPORTS

TOLUENE SNIFFING PRODUCING CEREBELLAR DEGENERATION

DANIEL A. GRABSKI, M.D.¹

Despite the wide-spread use of tobacco, the intake of intoxicants via the respiratory tract through inhalation, or sniffing, is infrequently reported. Modern industrial technology has produced a wide variety of solvents, the volatility of which makes them readily available to inhalation. The following case will demonstrate the consequences in one case.

H.J.B. was hospitalized for the first time in January 1954, at the age of 21. He stated that approximately 2 years earlier, while working in an aircraft factory he was assigned a job cleaning items in a solvent he identified as Toluene. While working over a large container of the substance he had inhaled its vapors, liked their smell, and the "dizzy effect" or euphoria he experienced. This led to experimentation and he inhaled the vapors of various other solvents. He claimed gasoline had a very euphoric effect and would use this when Toluene was unavailable. Isopropyl alcohol was without effect. Trichlorethylene and methylethylketone smelled bad and were rejected. He solved his Toluene supply problems by purchasing the chemically pure (CP) substance in gallon lots from a paint store when he could no longer filch Toluene of analytic reagent purity from the aircraft company's laboratory (he was quite concerned about using only a pure substance). He continued to use this drug by inhalation until he was hospitalized. At this time his mother stated the patient would frequently spend time at home clutching a rag he had soaked in Toluene to his face inhaling its vapors. This bizarre behavior did not cause family concern until mental confusion, dizziness, inappropriate laughter, staring into space and threatening suicide made hospitalization necessary. Physical examination on first admission revealed evidence of cerebellar disease, as well as hepatomegaly and impaired liver function. Psychological testing was more compatible with a schizophrenic disorder than of

organic brain disease, although the overall clinical impression was that of a primary personality disorder with secondary toxic symptoms produced by Toluene inhalation.

The patient has been hospitalized 3 times since under essentially similar circumstances. On his most recent admission, in 1958, neurological examination revealed the following:

Orientation, memory and intellectual functioning were within normal range.

Olfactory sense intact.

Eyes showed only slight nonpersistant nystagmoid movement on lateral gaze. Fundi: normal.

Cranial nerves, 5,7,9,11,12, no evidence of abnormality.

Deep tendon reflexes, of moderate intensity, equal bilaterally.

Posterior column signs, toe position and vibratory sense intact. Bilateral equivocal Babinski sign with negative Gordon, Oppenheim, and Chaddock.

Muscle tone and muscle bulk within normal limits.

Gait: classical titubating gait with redundant movements characteristic of cerebellar disease involving the lateral lobes.

Cerebellar signs: intention tremor of both hands and feet, more pronounced in the hands. Mild adiadochokinesis in the upper extremity; rebound phenomena in both arms and legs. A drift phenomenon was not demonstrated.

Superficial reflexes: abdominals equal bilaterally, cremasterics absent.

Sensory examination: two point discrimination, pain discrimination within normal limits.

The possibility of multiple sclerosis or a familial cerebellar disease was considered and excluded following evaluation of the family members, and the absence of any eye difficulties at any time in this patient. The final impression was of a degenerative lesion of the lateral cerebellar lobes due to prolonged inhalation of Toluene vapors.

Toluene is a highly toxic, aromatic solvent used extensively in industry and readily available, although fortunately rarely used, for inhalation purposes. The chemical

¹ Dept. of Psychiatry, 5812 Beach Blvd., Buena Park, Calif.

formula is $C_6H_4CH_3$, a methylated benzene ring. The substance is available under the commercial name of Toluene, Toluol, or Methylbenzene. Its toxicity rating is 4, which is considered very toxic; 50 to 500 mg. per kg., or 4 to 30 ozs., for a 70 kg. man are considered a fatal dose(1). The toxicity is similar to a related group of aromatic hydrocarbon solvents such as benzine, cumene, and mesitylene. These substances are commercially found as contaminants of one another and are widely used in industry. They may be found around the home in paint removers, degreasing cleaners, lacquers, insecticides, pesticides, and plastic cements. All of these aromatic hydrocarbons produce basically similar types of reactions, namely, local irritation, central nervous excitation and depression, and bone marrow inhibition.

Psychiatrists will undoubtedly see more

and more patients who have sought refuge from their personality disturbances through the inhalation of aromatic or aliphatic solvents(2, 3) and may overlook the serious toxic effect of these drugs. Cerebellar signs, in particular, are easily overlooked. Tremors may be passed off by patient, family, and even examining physician, as "nervousness." Toluene can produce irreversible cerebellar degeneration among its other toxic effects and the cessation of its inhalation must be considered emergent in the psychiatric treatment of this type of addiction.

THE PRESIDENT'S PAGE

DO WE HAVE A POSITION ?

The aphorism that nothing that is human is foreign to psychiatry is a commonplace. Occasionally one encounters a more caustic corollary to the effect that it is no great challenge to a gentleman of the press to elicit a psychiatric opinion on virtually anything from the foibles of the Roman emperors to the frustrations of the suburban housewife.

Be that as it may, however prone to public pronouncement the individual psychiatrist may be, one detects no such alacrity among psychiatrists to express themselves collectively through their Association.

A major responsibility of our Association (and of other professional associations in their fields) is to counsel the community on matters that fall within our professional competence. That is one good reason why the community confers a special status on us as a non-profit, tax-exempt, educational organization.

We accept and discharge that responsibility in several positive ways. We publish standards for psychiatric facilities. We alert the public to dangers in the irresponsible use of hypnosis and tranquilizers. We take official positions on the confidentiality of the doctor-patient relationship and on psychotherapy in medical practice. Less officially, but probably even more influentially, we perform our counseling function by setting up boards and committees to screen what shall appear in our reports and journals. Beyond that we have a staff facility which responds to thousands of requests for information and opinion on our stationery.

We also render counsel by refusal to take a position, by failure to respond, since negation is quite as subject to interpretation as affirmation. It is possible that we rely too heavily on this device. To the extent that failure to respond is the product of necessity or thoughtful intent, it may indeed be the only or the wisest course of action. The bothersome question is whether our use of the device is the product of necessity or thoughtful intent or oftentimes the product of

something less salutary.

This is not to suggest that collective psychiatry should burst into print with official opinion on the deleterious effects of television on children, or the Berlin crisis. Still, a debater's brief is easily mustered to the effect that we, the Association, have been excessively timid in delineating the area of competence in which we owe a rendering of counsel to the community.

Every psychiatrist to his own illustrations.

It seems a little strange to this writer, for example, that our Association has no opinion on the Kefauver-Celler Bill. How many members know what it is ? In a sentence it would restrict the production, marketing and patenting of drugs until their safety and effectiveness is fully validated. The American Medical Association and pharmaceutical manufacturers oppose the bill in the general conviction that it would lead to undesirable Federal controls.

Surely here is an issue of deep and special concern to us. We use a lot of drugs. Who among us had not expressed indignation and shock at the excessive and unproven claims attendant on advertising the birth of a new tranquilizer ? Shall we let it be assumed that as physicians we "go along" with the position of organized medicine ? Perhaps we do. But it is possible that collective psychiatry harbors a conviction that present agencies and techniques for drug evaluation, marketing, and promotion are inadequate and that more rigorous measures are indicated. If so, should we not offer our counsel to the community on the Kefauver-Celler issue ?

Take the Kerr-Mills bill which proposes a Federal matching grant program to encourage state expenditures on medical care for needy aged people. The Kennedy administration has a counter proposal that would eliminate any means test and make medical care for the aged available to everyone eligible under the Social Security system. How do we, the psychiatrists, feel about it ? And especially, what would we say if neither proposal provided any bene-

fits for otherwise eligible aged but mentally ill persons? Shall we allow others to speak for us on this issue, too?

So much for just two examples. It almost seems that an issue must actually invade the area of psychiatric clinical practice if it is to stimulate a reaction from psychiatrists collectively. Such issues as the drug problem and medical care to the aged are apparently considered a little too peripheral to capture our collective concern. So we fail to respond with counsel, even though it is manifest that any resolution of these issues will drastically affect our clinical practices.

Our Association, through its Council, Committees, and Staff, has ample facilities that could be used more intensively for the transmission of counsel to the community. Should we not proceed to use them to this end?

Many World War II veterans among us will recall the old military quip, "Well, let's raise the flag, boys, and see who salutes." These comments are in the nature of such a flag raising. Will anybody salute?

WALTER E. BARTON, M.D.,
President.

PARITY IN NURSING EDUCATION

The theme that emerged from an early Mental Hospital Institute was the "Therapeutic Community". In a discussion on Nursing at a subsequent Institute it was noted that the number of professional nurses employed in mental hospitals had decreased almost to the vanishing point and that the only state systems which could obtain any significant number of professional nurses were those which provided undergraduate training programs. The available statistics indicate that the situation has not improved and one wonders whether there has been much effort to improve it. Albee states in passing "... no nursing leader has suggested a return to the practice of training nurses in schools located in mental hospitals..." However nursing leaders generally are very enthusiastic about providing a period of experience and formal instruction in psychiatric nursing for undergraduates in the general nursing course.¹ When the question of providing schools of nursing in mental hospitals is raised the answer is that they would be acceptable if they could meet the standards. This seems fair enough if it did not always seem to carry with it the implication that, of course, they could not really be expected to meet the standards.

The attitude of mental hospital administrators is a little difficult to determine. Some maintain that they can prepare other categories of personnel who will be better qualified to function as key personnel in the "therapeutic community" than is the professional nurse. Can we accept this opinion at its face value or is it a tacit acceptance of the impossibility of providing in mental hospitals a high standard of basic training for professional nurses or of obtaining professional nurses trained elsewhere?

The question may well be raised "why make so much of the professional nurse, or why confine the term to the general-trained

registered nurse?" Some jurisdictions have raised mental hospital nurses without general training to the professional level but the sponsors are quick to assert that these nurses get as satisfactory training in the physical care of the patient as the general nurse. Nevertheless they cannot get recognition as having equal competence to provide physical nursing care.

Theoretically nursing educators agree that the nurse should be able to apply her skills to the care of the "whole person". Theoretically the basic training of the psychiatric nurse and of the general nurse should be very similar. This cannot possibly be provided in social structures as different as the general hospital and the mental hospital. However there seems to be a good possibility that in the future general hospitals and mental hospitals will resemble each other more closely. In such an event it would be expected that the general nurse and the psychiatric nurse would develop similar competence to meet the needs of the patient.

In Ontario we have had the collaboration of the Nursing Branch of the Department of Health in redesigning the course for undergraduate nurses in 3 mental hospitals. (Essentially the function of the Nursing Branch is to set standards for and to inspect schools of nursing throughout the province.)

In this collaborative effort particular attention has been devoted to evolving more effective methods of studying the "whole person" and his interaction with his environment. The basic course which has been designed for the purpose embodies the elements of the physical and social sciences essential to the development of skills in nursing and should be applicable equally to training for general and mental hospital nursing.

The basic course of 9 months is taken in the "home" school and is followed by 15 months affiliation in a general and a children's hospital. Although, since 1937, at least one year's affiliation in grade A gen-

¹ In Ontario the mental hospitals provide 3 month affiliation courses for about 1,800 students from general hospital schools of nursing each year.

eral hospitals has been provided for undergraduates training in mental hospitals, the new relationships that have been developed are providing for better integration of the students in the affiliate hospitals.

The first 2 years, including affiliation, are essentially academic. The third year, taken in the "home" school, is devoted to psychiatric nursing in the mental hospital and its community services.

The student who successfully completes the 3 years is eligible to sit the examination for the R.N. As an R.N. she is able to qualify for employment as a general nurse in any type of hospital or in private practice. At the same time she has the advantage of much more extensive training in psychiatric nursing than is provided by the usual psychiatric affiliation.

With the beginning of the new course stipends were increased, bursaries made available and recruiting drives were carried out by each school of nursing in its own hospital area. These efforts have been rewarded by a great increase in the number and quality of applicants, and the enrolment, after more careful selection, has more than doubled.

The fear is sometimes expressed that training that will fit nurses to obtain employment in general nursing will only encourage the nurse to leave the mental hospital. This is an expression of distrust of our ability to make employment in the mental hospital interesting and congenial. This is a risk that we are prepared to take because previous experience with general nurse training has been reassuring.

The efforts outlined above can only be justified on the assumptions that the nurse's role is still relevant to the care of sick people, that the nurse is the doctor's most appropriate assistant and that the nurse with combined training is likely to be more competent in the care of patients and particularly in a responsible supervisory role. These assumptions are made on the condition that programs of nurse training will ensure that the nurse is prepared to use the interpersonal skills which are relevant to her function in the therapeutic process.

CORRESPONDENCE

MONISM AND DUALISM

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR : Dr. Levin's article on Monism and Dualism in the July issue of the *Journal* will leave those of us who are interested in philosophy utterly bewildered. He tries to prove Dr. Bailey's "mistake" by discussing the views of Hughlings Jackson, whom he represents as a "monist." He quotes the following passages :

The doctrine I hold is : first, that states of consciousness (or, synonymously, states of mind) are utterly different from nervous states ; second, that the two things occur together, that for every mental state there is a correlative nervous state ; third, that, although the two things occur in parallelism, there is no interference of one with the other. This may be called the doctrine of Concomitance.

This view, of course, was not introduced by Jackson, but is the well-known philosophy of Leibnitz. I am sure that Jackson expected his readers to realize this because Leibnitz was well known in Jackson's time. It is the strongest expression of dualism ever proposed. Mind and Matter (Leibnitz thought) are concomitant, but independent, like two clocks, one of which has hands to show the hour, the other a gong to ring the hour. If they are synchronous, a casual observer may believe that the fact that the gong of one clock rings when the hands on the other clock show the full hour must be based on an "interaction" between the clocks ; actually, they are merely synchronous. The Lord has created the world so perfect that this synchronism is established forever. Jackson's only reservation was that being a physician, not a philosopher, he would not have to say anything about the reason for the synchronism, and did not need Leibnitz's religious explanation.

Having quoted Jackson's belief in the theory of Parallelism, Dr. Levin continues : "To put the matter into other words, mental states are but the epiphenomena of physical

states in the brain." This, however, is not "putting the matter into other words" but rather presenting an entirely different, though equally well-known theory, the theory of the mind as epiphenomenon. It is difficult to imagine that someone could identify or combine these two, for Parallelism is dualistic ; it needs two parallel concepts—there are no "one-piece parallels." The theory of the epiphenomenon (originating with the ancient atomist, Democrit, etc.) is monistic. Here the assumption is that there is *only* Matter ; what appears as Mind is nothing more but like the flame which appears as an epiphenomenon when wood oxidizes ; a spectacular, but in itself non-existing, meaningless epiphenomenon.

While I was still pondering which of these views Dr. Levin accepts, or how he can combine them both into one theory, I was suddenly finding myself confronted with a third, again different theory. "Psychic event *can* influence behavior" we are suddenly told. He presents a "Theory of Interaction." Why it should be important whether interaction is immediate, or "mediated by cerebral mechanism" (or maybe by pineal mechanism, as the famous dualist Descartes thought), is a bit difficult to understand. It's interaction and dualism in any case. If *one* can influence the *other*, we are dealing with two phenomena, and so have now switched back to dualism and to Dr. Bailey's claim of the implied dualism in psychodynamics, which Dr. Levin tries to deny.

What is that "Mind" which can influence the body ? Is it Plato's substantial Mind ? Kant's transcendental Mind ? Dr. Levin does not tell us ; and his example of the child who was scared by a dog and shows behavioral changes later on is not illuminating, either. What happened when the child was "frightened by a dog ?" A physiological fright reaction with body influencing mind ? Or maybe a psychological trauma with mind influencing body ? Concomi-

tance? Epiphenomena? Interaction? Which one is it?

But must we psychiatrists continue to fight each other's philosophy? Is there none which provides a basis suitable for all? Many modern scientists (including Albert Einstein) find the philosophy of Spinoza strangely modern. Benedict Spinoza, the heretic philosopher, believed that there is only *One* world. But it is like an optical lense with two surfaces, one convex, and the other concave. These may appear like two different, independent phenomena to an observer, for he sees nothing else. But actually these two surfaces are indivisibly

One. And so (Spinoza feels) *Reality* is only *One*, but offers two aspects: Body and Mind, Matter and Spirit. Each change of this reality will affect both aspects (though not necessarily in the same degree). Here we have neither independent concomitance, nor an epiphenomenon, nor an interaction. But an identity of the psychobiological organism, which merely appears to us human beings as a dual phenomenon. Would not such a philosophy, I wonder, suit both, Dr. Bailey as well as Dr. Levin?

Hans S. Unger, M.D.,
Buffalo, N. Y.

REPLY TO THE FOREGOING

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY:

SIR: Prudence warns me not to engage Dr. Unger in a dispute over the meaning of monism and dualism, as his competence in philosophy is obviously greater than mine. The object of my article was to invite attention to some concepts, mainly those of Hughlings Jackson, which appear to be of value to the psychiatrist and the student of behavior. I stand by the substance of the article, but will entertain criticism as to the propriety of the philosophical terms I have used.

Monism and dualism have many different meanings. I use the terms in the sense of Lord Cohen, who wrote, "The ultimate goal of science is a universal monism." In the same sense the chemist Wilhelm Ostwald, as reported by Heinrich Klüver, declared at the turn of the century, "I open the monistic century." In this usage the monist, it seems to me, is he who believes that all behavior (including mentation, which is internal be-

havior) is the product of cerebral activity. Psychic activity is "concomitant" with cerebral activity.

Dr. Unger says that Jackson's doctrine of concomitance is "the strongest expression of dualism ever proposed." This is hard to accept (in the sense of Lord Cohen and Ostwald). Jackson was a monist and nothing else. The exponent of dualism was Laycock, as shown by the citations given in my article.

Mind and brain are two things, and *dual* means two, but this is a mere accident of semantics, and not a reason to designate psychophysical parallelism as dualism.

A minor point: I do not claim that Jackson introduced the doctrine of concomitance, nor did he. Jackson named a dozen earlier writers (including Leibnitz) who had proposed essentially similar ideas. (See the *Selected Writings*, volume II, page 84.)

Max Levin, M.D.,
New York, N. Y.

NEWS AND NOTES

FELLOWSHIPS, NEUROPHYSIOLOGY, NEUROANATOMY.—New York University Medical Center is offering a 3-months Training Fellowship with stipend of about \$1,000 in neuroanatomy and neurophysiology, beginning March 1, 1962. Candidates holding the M.D. or Ph.D. degree and interested in teaching or research in these subjects are eligible. Applications should be in by January 1, 1962. For information apply to: Dr. Louis Hausman, department of anatomy, New York University School of Medicine, 550 First Ave., New York 16, N. Y.

LINDAUER PSYCHOTHERAPIEWOCHE.—The 12th Lindau Psychotherapy-week will be held from April 30-May 5, 1962. The main items will be the physical symptom as psychotherapeutic problem. In 2 morning sessions the theme "Psychotherapy in Medical Institutions" will be dealt with. In afternoon sessions there will be opportunities for practical experience in the important phases of psychotherapy. Related exercises will be dealt with during the week.

For information write to the Secretariat of the Lindauer Psychotherapiewoche, München 2, Dienerstr. 17.

BIRTH CONTROL.—*New Medical Materia*, Sept. 1961, publishes the results of that journal's latest survey in which several thousand doctors participated: 44.1% of obstetricians and gynecologists and 25.3% of general practitioners give birth control advice routinely; 50.7% of all doctors give such advice on request of patients; only 17.7% of all doctors reported that they never gave such advice.

The returns published were not broken down as between Catholic and non-Catholic doctors.

U. S. PUBLIC HEALTH SERVICE SUPPORT OF COMMUNITY MENTAL HEALTH SERVICES.—Funds budgeted for this purpose during 1961 totalled \$91 million, an increase of about 100% since 1957.

An analysis of State legislative actions made by the National Institute of Mental Health reveals that during the current year 8 State legislatures enacted major new legislation affecting community mental health. In one year 1960-1961, total Federal, State, and local funds budgeted in State plans for these purposes increased by 41% from \$65,000,000 to \$91,000,000. The latter figure included Federal funds amounting to \$6,000,000—less than 7% of the total. Ten years ago, Federal funds accounted for 27% of total budgeted funds.

Under provisions of the National Mental Health Act passed in 1946, all the States and Territories now share in Federal funds which are allocated on the basis of the State's population and financial need. Under regulations all States must match every dollar of Federal aid with one State dollar.

ACADEMY OF PSYCHOANALYSIS OFFICERS AND TRUSTEES, 1961-1962.—*President*, Roy R. Grinker, Sr., M.D., Chicago, Ill.; *President-Elect*, Sandor Rado, M.D., New York, N. Y.; *Past-President*, Frances S. Arkin, M.D., New York, N. Y.; *Secretary*, Joseph H. Merin, M.D., New York, N. Y.; *Treasurer*, John L. Schimel, M.D., New York, N. Y.; *Trustees*, Nathan W. Ackerman, M.D., Irving Bieber, M.D., Ralph M. Crowley, M.D., Marianne H. Eckardt, M.D., Don D. Jackson, M.D., Janet Mack Rioch, M.D., May E. Romm, M.D., Leon Salzman, M.D.

The mid-winter meeting of the Academy will be held at the Hotel Commodore, New York City, Dec. 9-10, 1961. The main subject of the 2-day meeting will be Psychoanalytic Education.

DR. GITELSON HONORED.—At the last Congress of the International Psycho-Analytic Association in Edinburgh, Scotland, in July 1961, Dr. Maxwell Gitelson of Chicago was elected President. In this office he is successor to such eminent men as Ernest Jones, Jung and Abraham.

At the present time Dr. Gitelson has tak-

en temporary leave from his practice to accept the visiting Sloan Professorship at the Menninger Clinic.

DIVISIONAL MEETING N. Y. STATE BRANCHES APA.—This biennial meeting will be held Nov. 10-12, 1961, at the Hotel New Yorker, New York City.

The theme will be a multi-disciplinary report of studies on human behavior by scientists, philosophers, and psychiatrists. Among topics to be discussed will be The Biochemistry of Behavior, Genetics in Psychiatry, Physiological Basis of Behavior, and Animal Behavior.

Six scientific sessions and 4 panel meetings are planned for the 3-day meeting.

DR. CLOUTIER TO HEAD WORLD FEDERATION FOR MENTAL HEALTH.—Dr. François Cloutier, F.R.C.P. and a member of the American Psychiatric Association and the Canadian Psychiatric Association, likewise the Association of French speaking Physicians, has been appointed Director of the World Federation for Mental Health succeeding Dr. J. R. Rees of London.

Dr. Cloutier will take office in January 1962. He is a resident of Montreal.

DR. KETY SALMON LECTURER, 1961.—The annual Thomas William Salmon Lectures

will be delivered on Monday, December 4, at the New York Academy of Medicine, 2 East 103rd Street, New York, at 4:30 P.M. and 8:30 P.M.

The 1961 lecturer will be Seymour S. Kety, M.D., Henry Phipps Professor of Psychiatry at the Johns Hopkins Medical School. Dr. Kety will speak on "The Implications of Biochemistry for Psychiatry," discussing in the first lecture "The Basic Chemistry of the Nervous System," and in the second "The Application of Biochemistry to Problems of Psychology and Psychiatry."

The Salmon Lectures, which have been given since 1932, are under the aegis of the Salmon Committee on Psychiatry and Mental Hygiene. The committee is appointed by the Council of the New York Academy of Medicine. The Lectures are published later in book form.

ISRAEL S. WECHSLER LECTURE.—Dr. Oliver H. Lowry, Professor and Director of the Department of Pharmacology, Washington University School of Medicine, St. Louis, Mo., will deliver the seventh annual Israel S. Wechsler Lecture on December 8, 1961 at 8:30 P.M. in the Blumenthal Auditorium of the Mount Sinai Hospital, New York City.

Dr. Lowry's lecture is entitled: "Challenges in the Study of Brain Chemistry."

OUTGROWING WAR

The human record began with warfare, which will remain a dominant occupation until mankind attains a spiritual level higher than that of any of the gods he has feared and worshipped.

BOOK REVIEWS

ACTION FOR MENTAL HEALTH. The Final Report of the Joint Commission on Mental Illness and Health. (New York: Basic Books, Inc., 1961, pp. 338. \$6.75.)

Billed as a "Program for Meeting the National Emergency," the report provides much that is useful for future programming but makes its greatest contribution in bringing together the consensus of leading authorities, providing material on certain studies carried out for its purposes, and broadening the vision of mental health planning toward an appreciation of basic conditions which underlie some of the formidable problems of today.

This volume is, in part, a summation of the work of the members of the commission, the staff, and editors, task forces, advising committees and consultants who, guided by the Committee on Studies, finally produced 10 volumes. The titles of these suggest the scope and depth of the total effort. These are: *Current Concepts of Positive Mental Health* (Marie Jahoda); *Economics of Mental Illness* (Rashi Fein); *Mental Health Manpower Trends* (Albee); *Americans View their Mental Health* (Gurin, Verhoff, Feld); *Community Resources in Mental Health* (Robinson, DeMarche, Waggle); and *Epidemiology and Mental Illness* (Plunkett, Gordon). These are now available from Basic Books, Inc., NYC. In preparation: *The Role of Schools in Mental Health* (Allin Smith, Goethals); *the Churches and Mental Health* (McCann); *New Perspectives on Mental Patient Care* (Schwartz, Schwartz, Field, Mishler, Olshansky, Pitts, Rappaport, Vaughan); and *Research Resources in Mental Health* (Soskin). Recommendations are summarized in the beginning and also discussed in the final chapter. They contain 4 main headings:

I. *Pursuit of Knowledge*: An important contribution is the philosophy "that science and education are resources like natural resources—and that they deserve conservation through intelligent use and protection and adequate support—period." "What is most needed (in Research) is a balanced portfolio," with emphasis on basic, long-term, diversified support of persons and ideas assuming the necessary calculated risk. The need is for capital support for careers—careers made attractive enough to hold young scientists and offering assistance to eligible educational institutions. The report endorses the Jones Report (U. S. Senate Committee on Appropriations, 1960). Since the

volume on Research is not yet out, no comment can be made on the justification for these points of view. They appear, however, to coincide with commonly accepted ideas.

II. *Better Use of Present Knowledge and Experience*: (A) *Manpower*—A major contribution is made toward recognition of the deficits in the manpower pool from which mental health personnel are drawn. (B) *Relations of Mental Health Manpower to the Whole Field of Education and Career Choice*—but solutions to what are presented as insolvable shortages do not differ from ideas which have been commonly mentioned for sometime and these are not specifically presented.

There is reason to believe that somewhat more optimism is justified in the light of developments in social psychiatry and the shift in methodology which appears to be in the making. The recommendation for income tax deduction for educational expenses is an interesting approach towards increasing the responsibility of individuals for general education in their own families. The comments on the uses of volunteer services and the place of churches in mental health are useful but leave a sense of imbalance since college students are not often available and use of volunteers is increasing fast in other ways. Useful sections include: services to mentally troubled people (defined as mentally ill in early stages), immediate care, intensive treatment of acutely ill, and care of chronic patients gives a review of a variety of approaches. Suggestions as to the use of large state hospitals are controversial and impractical but may aid progress because of their provocative nature. Sections on after-care and rehabilitation services are especially good, but it could be added that Day Hospitals, etc. are equally valuable in diverting a patient from entering a hospital or assisting him after he leaves. Again, the volume on "New Perspectives on Mental Patient Care" is not yet available and we do not know how well the justifications are developed for the specific recommendations.

III. *Public Information on Mental Illness*: Lays the basis for a sound program for citizen groups.

IV. *Cost*: The major thesis is: "Expenditures for public mental patient services should be doubled in the next 5 years—and tripled in the next 10." The principal recommendation is that states and federal government should share the cost of state and local mental patient

services with federal government providing up to one-third of state costs. This is not as radical as it sounds considering the growth in public assistance and social security funds emanating from the federal government, but it is another large step towards federalization of local services. Emphasis in increased services and a sound standard of care and treatment would have been more valuable.

The commission report neglects to make any mention of the formidable array of individual, private, and voluntary hospital services which already furnish an appreciable amount of the psychiatric services in the nation. Therefore, the statement, "Our proposal is the first one in American History that attempts to encompass the total problem of public support of mental health services and to make minimum standards of adequate care financially possible" must be criticized for its assumption that public support shall encompass the total problem. This is both contrary to the present situation and contrary to American tradition. For example, in one state last year, 25,000 admissions to state hospitals occurred while, at the same time, 22,000 admissions were received in non-governmental, licensed mental institutions and 24,000 admissions in psychiatric units of general hospitals, some of which were voluntary hospitals and some of which were county hospitals. The commission might have made an equally radical recommendation in the opposite direction. That is, that responsibility for the cost of psychiatric treatment services be shifted from the current 65% tax support and 35% non-tax support to a 50-50 division of responsibility between individual, private and voluntary resources, including prepaid insurance on the one hand, and federal, state, county, and municipal tax resources on the other (the California Plan). The commission also overlooked the opportunity to demand parity for persons with mental disorders in terms of equal sharing of federal monies from public assistance, total disability and old age medical care (Kerr-Mills Bill) as are received by persons suffering from other diseases.

A glaring omission is the lack of reference to mental retardation which is the second in the list of 7 major categories of mental disorders named in the official nomenclature of the A.M.A. and APA. The Cinderella of mental disorders is thus delayed another eon of time in finding her golden slipper. The fact that NIMH had made a sizable grant to the National Association for Retarded Children to study retardation does not justify the omission. Periodic reference on how subject matter treated in this comprehensive report also applied to mental re-

tardation would have been easy and quite helpful.

The staff, particularly the Director, Dr. Jack Ewalt, and Mr. Greer Williams, who is responsible for its clarity, punch, and forceful diction, deserve great credit and the thanks of the nation. In spite of some omissions, this volume and all 10 volumes are strongly recommended for careful reading and study.

DANIEL BLAIN, M.D.,
Sacramento, Calif.

THE NEUROCHEMISTRY OF NUCLEOTIDES AND AMINO ACIDS. A Symposium of the Section on Neurochemistry, American Academy of Neurology. Edited by *Roscoe O. Brady* and *Donald B. Tower*. (New York: John Wiley & Sons, Inc., 1960, pp. 292. \$10.00.)

For a long time, carbohydrate metabolism has occupied the center of the stage in neurochemistry but interest is now focussing more and more on the metabolism of nitrogenous and lipid substances. The present volume is a record of the transactions at a symposium organized by the Section on Neurochemistry of the American Academy of Neurology, held in April, 1958.

The book's first part is mainly devoted to an account of the acid-soluble nucleotides and their coenzyme functions, most of them applying to nervous and non-nervous tissue alike. Topics of neurochemical interest include the function and occurrence of guanine nucleotides in brain, the role of cytidine nucleotides in the biosynthesis of phosphatides and of uridine nucleotides in the biosynthesis of cerebroside, and the neurological effects of the acetylpyridine analogue of nicotinamide dinucleotide. The last chapter of this section, misleadingly entitled "Neurochemistry of Polynucleotides" is for the most part a study of the *in vitro* interaction of nucleic acids and related polymers with a fluorescent dye. Important though its implications may be, it seems somewhat out of place. Only passing reference is made to the work of Caspersson; that of Hyden or Edström is not mentioned at all although it offers perhaps the richest promise of linking polynucleotide metabolism to neural function.

The second part of the book deals with selected aspects of the neurochemistry of amino acids and their derivatives. Neurohormones, monoamine oxidase activity and phenylketonuria are briefly surveyed. The metabolism and possible function of γ -aminobutyric acid in the brain and the microdistribution of the principal enzymes responsible for its formation and breakdown are expertly reviewed. Asparagine

and glutamine are the subjects of another detailed discussion. In the final chapter, experiments bearing on the metabolism and turnover of brain proteins are reported.

The formal papers are followed by discussions. In a final summing-up, the editors fill in some gaps, take stock of the present position and assess the outlook for future research.

The contributions are, on the whole, well-written, concise and competent. They provide a useful introduction to the field.

H. WEIL-MALHERBE, M.D., D.Sc.,
Saint Elizabeths Hospital,
Washington, D. C.

RECENT ADVANCES IN BIOLOGICAL PSYCHIATRY.
Vol. III. Ed. by *Joseph Wortis, M.D.* (New York and London : Grune & Stratton, 1961, pp. 241, illus., \$9.75.)

In his foreword, Editor Wortis speaks of the origin of the Society of Biological Psychiatry in 1947 and its purpose to give fresh emphasis to "the neural, the neurologic, the physical, the physiologic side of psychiatry—at the time when psychological, and especially psychoanalytic, aspects of psychiatry were being so strongly emphasized that the physical basis of mind was often neglected or forgotten." Membership in the Society "has always been limited to those who have demonstrated their capacity for experimental work."

The present volume contains the scientific papers read at the 15th annual meeting of the Society in June, 1960.

Hoch, in his presidential address, reviews the great gains that biological psychiatry has made in recent decades in the treatment of many forms of mental illness, and points also to areas where more intensive work must still be done, particularly where etiology is so obscure. He sees psychological activity as part of the total biological functioning of the individual, and psychotherapy simply as a feature of the total treatment process. He points out that the pharmacological treatment of schizophrenia "is symptomatic and not etiological," and that "appraisal of the efficacy of these new treatments should be done effectively, devoid of the usual sniping that they are no good because they do not fit into certain psychodynamic preoccupations."

Hoff of Vienna delivered the Academic Address, sponsored by the Manfred Sakel Foundation. He points to the hereditary taint in both schizophrenia and manic-depressive illness, this factor being more prominent in the latter. He traces psychological symptoms of schizophrenia due to defective energy metabolism in

certain brain areas "triggered by severe somatic or more often by psychological stress."

Hoff reports: "In most countries of the world, 39 percent of all patients suffering from relapsing depression die in the following 15 years by suicide."

Treatment of schizophrenia is adjusted to the form the psychosis takes. Insulin is regarded as "a basic therapy. It opens a door through which the patient may be reached." In Vienna at least 50 coma hours are usual. Group therapy, occupational therapy and drug treatment are also fitted into the therapeutic program.

Hoff describes also the carefully planned management of the endogenous depressions, relying heavily on ECT. "The shock treatment of endogenous depression is certainly one of the most successful forms of therapy in the whole field of medicine."

Lauretta Bender reports a very careful study of the vexed question of the relationship of childhood schizophrenia and epilepsy. Meduna (1937) had postulated that those two conditions were "biologically antagonistic." Hoch (1843) had concluded from an extensive study of adult patients that schizophrenia and epilepsy, while not pathologically related, were also not antagonistic to each other, in the sense that a given case could be considered schizophrenia with "symptomatic" epilepsy or epilepsy with "symptomatic" schizophrenia.

Bender analyzed 51 childhood cases considered schizophrenic that also had convulsive disorders. Thirty of these, she concluded were "essentially organic in etiology." In none of these 30 was there a clear family history of schizophrenia (in contradistinction to cases of "true" childhood schizophrenia). The remaining 21 cases showed either "typical epilepsy with schizophrenia" or were "typically schizophrenic" with atypical convulsive symptoms which did not yield to drugs normally effective in fits. Bender's findings were therefore essentially in agreement with those of Hoch 17 years earlier.

The fact that 68 research workers are represented in this book, either by original studies or in the discussion of the papers, is evidence of the expanding interest in the biologic basis of mental disorders and the fruitfulness of such studies as here described.

C.B.F.

THE SOCIAL EPIDEMIOLOGY OF MENTAL DISORDERS. By *E. Garfily Jaco.* (New York : Russell Sage Foundation, 1960, pp. 228. \$3.50.)

The author presents a study made in Texas

to check the reliability of, or add to, generally accepted concepts regarding demographic, ecological, social and cultural factors in mental disorders. In spite of most careful planning, execution and analysis, inconsistencies in the various racial, sex, age, geographic, educational, occupational, marital, religious and socioeconomic groups prevented drawing general conclusions regarding causal relationships in psychoses. Nevertheless, this is a very valuable report because it asks fundamental questions, emphasizes the need for answers, and provides a basis for further studies which might enhance our understanding of mental disease. The bibliography is extensive, the index complete, the format and printing of the narrative, tables and reproductions of high order. The report is to be highly recommended to all concerned with mental disorders.

N. E. MCKINNON, M.D.,
Epidemiologist,
School of Hygiene,
University of Toronto.

MEDICAL, SURGICAL AND GYNAECOLOGICAL COMPLICATIONS OF PREGNANCY. By The Staff of the Mount Sinai Hospital, New York City. Edited by Alan F. Guttmacher, M.D., and Joseph I. Rovinsky, M.D. (Baltimore: The Williams and Wilkins Co., 1960, pp. 604. \$16.50.)

This volume is the result of the collaboration of the staff of a large general hospital where consultants in all the various medical and surgical specialties have conducted clinics to which obstetrical patients suffering from a wide variety of complications have been referred and studied in detail. As a result, a reference book has been compiled giving authoritative answers to major and minor problems which may confront the obstetrician who undertakes the care of a pregnant woman.

To anyone who has practiced obstetrics for a long period of time it emphasizes the change which has taken place in adequate antenatal, intrapartum and postpartum care. No longer are the mechanical problems of childbirth the predominant responsibility of the obstetrician, but the modern obstetrical physician must have detailed knowledge of a wide range of pathological processes, the importance of these conditions being frequently accentuated by the metabolic strain of pregnancy.

The critic will search in vain for omissions in this comprehensive work. The section on heart disease presents an up-to-date consideration of this important complication. Haematologic problems and endocrine disorders, including diabetes, are dealt with clearly and in an

authoritative manner. The sections dealing with neurological complications and mental and emotional problems are particularly interesting especially as it is unusual to see them dealt with at length in an obstetrical text. Virus diseases and an appreciation of the basic problems of congenital abnormalities as well as the problems of malignant disease, both of the genital tract and breast, are outstanding features of this excellent book.

W. G. COSBIE, M.D.,
Toronto, Can.

GENERAL ENDOCRINOLOGY. 3rd Ed. By C. Donnell Turner. (Philadelphia: W. B. Saunders Co., 1960, pp. 511.)

This is a completely rewritten version of a book which has established itself as a standard text on general endocrinology as a basic science. The approach is even more experimental than in previous editions, and while the importance of the applied viewpoint is recognized the purpose of the present volume is to convey the basic facts. The increasingly chemical development of the subject is reflected in the greater attention given to the chemistry of endocrinology, and there has been a greater addition of comparative material and an elimination of virtually all clinical references. The illustrations, the chapter references, and the text combine to make the present edition of *General Endocrinology* the most useful book of its kind.

HUMAN PITUITARY HORMONES. Vol. 13. Ciba Foundation Colloquia on Endocrinology. Edited by G. E. W. Wolstenholme and C. M. O'Connor. (Boston, Mass.: Little, Brown & Co., 1960, pp. 336.)

The Ciba Foundation Colloquium on human pituitary hormones was held in Buenos Aires in 1959, honoring Dr. B. A. Houssay, Argentina's distinguished endocrinologist. Over thirty leading investigators from Europe and the Americas contributed research data for discussion. Major emphasis was placed on human growth hormone with discussion of its preparation, purification, identification in human serum by immunological methods, and metabolic effects in human subjects. Preparation and purification of human follicle stimulating hormone was also discussed, along with observations of its effect in human beings. In conjunction with chorionic gonadotropin, human FSH has produced apparent ovulation in infertile females, a feat never accomplished with infra-human gonadotropins. Final sections of the

colloquium described experiences with new methods of measuring and isolating other human pituitary factors, adrenocorticotrophic, melanocyte stimulating, and thyroid stimulating hormones.

Informal discussion which follows each formal presentation contributes measurably to analysis of the data. The volume maintains the high standard set by previous Colloquia in Endocrinology, which have consistently provided recent reliable research reports and thoughtful discussion of new knowledge in the field.

PRINCIPLES OF HUMAN GENETICS. By Curt Stern. (San Francisco and London: W. H. Freeman and Co., second edition, 1960, pp. 753. \$9.50.)

In recording the publication of the first edition (1949) of "this masterpiece of an elementary textbook for students of human and population genetics" in the *Journal* (Vol. 107, p. 879), this chronicler was moved to place the event into the category of memorable occasions. What is more, he never had any reason afterwards to regret the choice of that superlative classification.

It is true that the appearance of the new edition (1960) was long in coming, obviously because of the many recent advances in the scientific areas covered. However, waiting a few years for the thorough revision has been definitely worthwhile. As to the size of the second edition it may be noted that it has grown considerably, from 617 to 753 pages and from 197 to 265 illustrations, in order to allow for a smooth incorporation of newly discovered data. The main thing is, however, that the superior standard of the widely used text has been maintained throughout. In fact, this is probably one of the first current books on human genetics that was not hopelessly outdated at the time it appeared in print.

While the general outline of the first edition has been more or less retained, it is significant that the new version of the book has undergone an imperceptible change in its mood. The nature of this change is best illustrated by the two formulations of a statement made in the introduction. In the first edition, the author conceded apologetically that "man is an unfavorable object for genetic study." In the second edition, this statement is formulated as follows: "At first sight, man appears to be an unfavorable object for genetic study." In this unobtrusive manner characteristic of the au-

thor's fine scholarship, the revised edition reflects that remarkable increase in the degree of confidence in the understanding of genetic phenomena in man, which was gained during the past decade.

Among newly added chapters is one concerned with "genetic hazards of radiation" (26 pages). The chapter "linkage and crossing over" has been subdivided into two, one dealing with different types of linkage, the other with the detection of linkage. The chapter on "heredity and environment" has been even more expanded and now consists of three separate sections entitled "types of twins"; "physical traits"; and "mental traits." The new chapter on mental traits begins with a series of examples taken from animal behavior studies, and the various sections dealing with the causes and effects of mutations have been similarly enlarged.

Of course, the new version of the section on "chromosomal sex" includes a lucid discussion of the cytogenetics of Turner's and Klinefelter's syndromes as well as of Barr's sex-chromatin bodies, and the chapter on "genic action" contains up-to-date information about the haptoglobins, the structure of haemoglobin, and the biochemistry of the sickle-cell trait. The formation of hybrid molecules in heterozygotes is briefly mentioned, while the section on inborn errors of metabolism still seems incomplete. On the other hand, the lists of references at the end of each chapter have been thoroughly revised and will prove to be helpful guides to further reading.

In the second edition, too, the most commendable features of the book are that the author neither talks down to the reader nor ever pretends that human genetics is without its own brand of technical difficulties and methodological dilemmas. Together with these dual qualities of modesty and scholarly integrity, it is the clearness of the presentation of a highly complex subject which makes the book what it was called 10 years ago, "an authoritative guide to the basic principles and dynamic potentialities of human heredity."

EPIDEMIOLOGIC METHODS. By Brian MacMahon, Thomas F. Pugh and Johannes Ipsen. (Philadelphia and Montreal: J. B. Lippincott Co., 1960, pp. 302, illus. \$7.50.)

This volume from the Department of Epidemiology, School of Public Health, Harvard University, presents common-sense methods for the study of health and disease. The authors

emphasize that there are many purely medical problems to be solved before attention can be spared for life's remoter troubles as noted in the WHO definition of health. They point out, too, and demonstrate that simple arithmetic suffices generally for the application of the methods presented. They repudiate any suggestion that any problem can be readily solved by merely turning a couple of epidemiologists loose on it for a couple of days. And they also demonstrate that competent analysis requires, as an imperative basis, a deep understanding of the primary data, their limitations, their attendant circumstances and related events.

The publishers are to be congratulated on the physical readability of the book, including the illustrations, on the attractive format and the complete absence of typographical errors.

CURRENT APPROACHES TO PSYCHOANALYSIS.

Edited by P. H. Hoch and J. Zubin. (New York: Grune & Stratton, 1960, pp. 207.)

This volume reports the proceedings of the 48th Annual Meeting of the American Psychopathological Association, New York City, 1960. The purpose of the symposium, according to the *Foreword*, was "... to bring together some of the outstanding current trends in psychoanalysis by providing a platform for representatives of each of these trends." The material is presented in 3 sections titled: Theoretical Approaches, Clinical Applications and Evaluation Studies.

In this type of forum, one would expect a concise presentation of the theoretical approach of each "school of psychoanalytic thought," rather than the introduction of new theoretical conceptions. Five theoretical approaches are summarized, beginning with Dr. Waelder's one-page outline of the psychoanalytic theory of the neuroses in its traditional application to the neuroses. He makes no allusion to the theoretical conceptions of ego psychology nor to modifications in technique that render it applicable to other psychopathological conditions; this is regrettable. After presenting a brief review of the development of Freud's theories, Dr. Sandor Rado outlines his theory of adaptational psychodynamics. Dr. Clara Thompson represents the views of Sullivan and Fromm as the theoretical framework of the W. A. White Institute and Dr. J. W. Vollmerhausen gives those of Horney, which are used at the American Institute of Psychoanalysis. Injury,

as a central point of reference in a concept of psychopathology, is discussed by Dr. Irving Bieber, representing the postgraduate training course at New York Medical College—Flower, 5th Ave. Hospital.

The round table discussion that follows is a bit livelier, with the "schools" represented by Drs. Sidney Tarachow, Lionel Ovesey, Edith Weigert, Harold Kelman and Saul Fisher, respectively. Dr. Ovesey is particularly forthright in stating those aspects of Freudian theory on which those who use the adaptational approach agree; those on which they disagree and which have been discarded and the results of applying the two frames of reference to one set of clinical observations. The knowledge and wisdom of Dr. Weigert are evident in her open-minded discussion of the various theoretical approaches and her ability to see the common ground and points of reconciliation among many of them. Her overview, which embraces some of the conceptions of a wide range of workers, is stimulating in its invitation to seek answers rather than to cherish theories.

The section on Clinical Applications includes papers on psychoanalytic method and technique by representatives of 3 of the schools, the classical and adaptational points of view being absent. This brief review of the volume cannot do justice to these detailed presentations.

The third part of the book, Evaluation Studies, contains provocative reports on 3 frontiers. Dr. David Levy writes on a method of analyzing clinical observations of relational behavior—a model of methodological procedure applied to an investigation of maternal attitudes. Changes occurring in patients during and after psychoanalytic treatment is reported by Dr. Henriette R. Klein. This study, carried out at the Columbia University Psychoanalytic Clinic by a cohesive group of investigators, evolves a method of evaluating patients' illnesses and responses to treatment. It is a pioneering effort that is continuing and that can contribute to the organization of similar investigations in other psychoanalytic centers. Dr. E. I. Burdock, a research psychologist and biometrician, is the senior author of a study, "Predicting Success in Psychoanalytic Training." How does one choose a candidate for psychoanalytic training who will successfully complete the course of training and emerge as a competent analyst? This report is a well organized effort to solve another methodological enigma and it broadens horizons for future investigations.

JAMES P. CATTELL, M.D.,
New York, N. Y.

TEXTBOOK OF MEDICAL PHYSIOLOGY. 2nd Edition. By *Arthur C. Guyton*. (Philadelphia : W. B. Saunders Co., 1961, pp. 1181, illustrated. \$15.50.)

This is an entirely rewritten version of a book which was first published in 1956, and upon publication was widely adopted as a teaching text. The enormous amount of labor the author has put into the writing of this book is abundantly justified by the results, for it undoubtedly constitutes one of the most readable, accurate, and certainly most up-to-date texts on the physiology of the human body. The illustrations are admirably clear, and the treatment of the human body as a single functioning organism controlled by a variety of regulatory systems, conveys the proper holistic view of the functioning organism.

In the discussion of the endocrinology of reproduction I miss an account of the steplike developmental processes involved, and I cannot help but think that there ought to be some reference to the physiology of the adolescent sterility period in the human female (as well as the male). But these are mere details. The book is quite admirable.

ASHLEY MONTAGU, Ph.D.,
Princeton, N. J.

SLEEP THERAPY IN THE NEUROSES. By *B. V. Andreev, M.D.* Translated from Russian by *Basil Haigh, M.A., M.B., B. Chir.* Edited by *Joseph Wortis, M.D.* (New York : Consultants Bureau Ent. Inc., 1960, pp. 114. \$8.50.)

The author reports on the material which had been collected since 1946 in the Pavlov Institute of Physiology. His conceptual framework underlying the sleep treatment is Pavlovian, mainly the concept of protective inhibition, and the contention that "many pathological phenomena are due, not to disturbance of the structure of nerve tissues, but to temporary inhibition, protective in character." The aim of sleep treatment consists "in the strengthening of this inhibition" which is "restorative and protective in character" in neuroses.

After a brief outline of the history of the method of sleep therapy, the author goes on to discuss the indication for such a treatment.

He indicates that "most of the authors who use sleep treatment think that, of all the various neurotic conditions, the best therapeutic results are attained in neurasthenia and neurasthenic states, especially in those with an asthenic symptomatology." There are disagreements as to the effectiveness of sleep therapy in hysteria and obsessional neuroses.

The method of treatment consists of the following points : 1. Preparation for the treatment ; 2. Forms of therapeutic sleep consisting of interrupted prolonged (fractioned) sleep, and prolonged nocturnal sleep ; 3. Daily program and environmental atmosphere ; 4. Physical hypnogenic factors, e.g. sound, temperature and weak rhythmic stimuli ; 5. The use of sedatives, mainly barbiturates and avoiding combination of sedatives ; 6. The use of inert substances (sedative substitutes) as conditioned reflex stimuli. This can be realized in some patients if it is used carefully, avoiding prolonged (for several successive days) replacement of sedative by inert substances ; and finally 7. The use of hypnosis and suggestion. The average daily sleep time is from 10 to 13 hours and the duration of sleep treatment from 1-3 weeks.

The author emphasizes repeatedly that "sleep therapy cannot nowadays be regarded as an independent and isolated method of treatment. It can only be effective in combination with other therapeutic factors, to be used in the subsequent period of the patient's stay in hospital or, in some cases, in the period of preparation for subsequent active psychotherapy."

As far as the immediate result of the treatment is concerned, of 87 patients 84% experienced "cure" or improvement. Of these, only 27 patients could be followed, 17 of whom "were in a satisfactory condition when we examined them" (time is undetermined).

The book ends with an extensive bibliography of the Russian literature given by the author, and a supplementary compiled by Dr. Wortis. The work as a whole, in addition to the bibliographies, is a valuable monograph for those interested in this subject.

Montreal, Can.

IN MEMORIAM

ROBERT A. MATTHEWS¹

1903-1961

Custom as well as spontaneous impulse and feeling bring us here today. Friends, relatives, family have gathered here. It is a Meeting, as so often in Philadelphia, without ceremony and ritual, where the Society of Friends has been accustomed to bring people together informally on the basis of community of feeling and dedication. This is a coming together to indicate by our presence many things.

There are many happy memories. The sparkle and alertness of the eyes, showing the keenness, the awareness of things obvious and often deeper implications than were first apparent. There was the not infrequent turning of his head and glance and attention to make sure those present were with him—that they knew and he knew what it was all about. There was a kind of social inclusiveness—his lines of sight with their comprehensive shifting and searching. There was a kindness and warmth and gaiety in his expression,—from the eyes, to the face, to the voice, with its expression of words, phrases, and opinions.

His observations and conclusions came readily but not impulsively and casually. They were restrained and kindly but had cogent, deep and forceful implications.

His pace and gait were lively but not driven. His greetings were friendly, whether the occasion was of serious business or for festivity. He had his repertoires whether of humorous stories and incidents, or of "telling" experiences which drove home a point. He had humor, which brought fun and balance to many occasions: whether his attempts to trim his hair short as a crew cut when there was not so much to clip, or his jolly little cap, or his white coat and black tie for formal occasions.

He had the psychological and the biological in balanced proportions in psychiatry. In his person and in his views the psychic

and the somatic were wholesomely represented.

And some of my memories run to Christmas Eve when, in Pickwickian attire and pixie mood, with solid friendliness and pride he brought his lovely help-mate and jolly children, full of spirit and enthusiasm. They all came to carol and drink a communion of friendship and neighborliness in the warmth of mulled wine.

Other memories also come of him: Doing a job and learning psychiatry, first in far off—at that time isolated, city managed, I was going to say almost zoological, Byberry. Or learning the refinements of psychiatry with Drs. Bond and Strecker in the comforts of the Pennsylvania Hospital. Or in gay New Orleans, where the distractions of Royal and Bourbon Streets, the delicious delicacies, exotic drinks, and jouncing jazz, did not too much divert him from the serious business of improving psychiatric care at the Charité. And as Chairman of the Department of Psychiatry at Louisiana State University he continually strove to improve the quality of psychiatric education in medical schools. The community and the state hospitals also felt his influence—he brought Maxwell Jones from far off England to conferences in the state hospitals.

He had fruitful collaboration with his colleague at Tulane—Bob Heath, who was exploring both the neurological and chemical aspects of schizophrenia, and modifying psychoanalysis.

His calmness, friendliness, resourcefulness, was shown when he was taking me from Biloxi to New Orleans to place me on a plane. He ran out of gas 100 miles from nowhere. I was wild—mildly turbulent as they say of a plane in rough, uncertain going, but I tried to contain myself. Then came his quiet reassurance that I should not worry and that he would arrive on time. Shortly a humble Cajun family in a doubtfully performing auto were pushing us 30 miles to a gas station. They refused any compensa-

¹ Remarks made at the funeral service in Philadelphia on June 27, 1961 by Kenneth E. Appel, M.D.

tion, though obviously in need of it with their huge family of children—so persuasive, so intriguing, was Bob Matthews' appeal.

In Charleston again, helping psychiatric education with his practical discussions on Emergencies in General Practice, or The Importance of Giving Psychiatric Information to the Police Force—giving them an elementary understanding of acute emergencies, the intransigencies and aberrancies of human conduct and how to handle them.

There in a day of delightful Spring weather, surrounded with Southern hospitality, he seemed receptive to tackling the Commissionership of Mental Health of Pennsylvania. With the determined, dedicated Harry Shapiro and the enlightened, sympathetic, Governor Leader, he introduced a new era in the care of the mentally ill in Pennsylvania. It was in his regime that the Western State Psychiatric Hospital with Dr. Brosin burgeoned into one of the great centers of psychiatry in the country; and then the Eastern Pennsylvania Psychiatric Institute, with the persistent and resourceful John Davis, got off the ground and was realizing a dream of a new development of psychiatry in Philadelphia where public psychiatry could offer not only the best in modern methods of treatment, but also could develop a phalanx of basic research, rising to refinements and penetrations that are representative of the best in the world. The state hospitals themselves felt this new influence, for development and progress, in their functions.

And finally in a historic professorship at the great Medical School at Jefferson—where Dercum, Strecker, Keyes, had been his predecessors, he showed leadership in developing psychiatry. He organized a large, successful, aggressive section of psychiatry in the great Jefferson Hospital. He established this with marked success—an undertaking that has been most difficult to achieve in Philadelphia Medical Schools.

With all this—teaching, explorations of new types of service, private practice—he did not abandon his efforts in behalf of public psychiatry, to improve the treatment of those who could not afford the best.

One of my last meetings was on the Med-

ical Board at the Eastern Pennsylvania Psychiatric Institute where we were searching for new methods and procedures in organization and practice. He contributed more than his share of resourceful suggestions to strengthen the foundations of that new institution, forging new precedents and instruments of research in a public hospital.

His home and family were a delight to enter.

There is a presence here we commemorate. It will always be in our hearts and its influences in our minds and decisions. As we commemorate, we dedicate our energies anew to the great and the constructive, taking with us his homely, humorous and balanced views of the ideal and the practical, dedications and directions for which Bob Matthews stood and lived.

Our love to his family and relatives.

When separations come, such as this, I always think of the great religious leaders of the world—but also of Socrates, Gandhi, Father Damien, Pasteur and Schweitzer—lives dedicated to the improvement of the lot of their fellow men. Plato concludes of Socrates: "such was the end of our friend." He was called wise, just and great. Bob Matthews will remain with us as friend, builder and co-laborer in the best of this great tradition. And from Avon come echoes, consoling, warming, energizing—as Bob Matthews would have liked.

"When to the sessions of sweet silent thought

I summon up remembrance of things past,
I sigh the lack of many a thing I sought,
And with old woes new wail my dear time's waste :

Then can I drown an eye, unus'd to flow,
For previous friends hid in death's dateless night,

And weep afresh love's long since cancell'd woe,

And moan the expense of many a vanish'd sight :

Then can I grieve at grievances foregone,
And heavily from woe to woe tell o'er
The sad account of fore-bemoaned moan,
Which I new pay as if not paid before.
But if the while I think on thee, dear friend,

All losses are restor'd and sorrows end."

FRANKLIN S. DuBOIS, M.D.
1906-1961

To the many friends of Franklin S. DuBois, his death on June 24 brought deep distress, but to those of us who worked with him, through the years, on the staff at Silver Hill, where he was Associate Medical Director, it meant irreparable loss as well. His knowledge of neuroanatomy and neurophysiology, and of internal medicine was a broad base on which his knowledge of psychiatry stood, giving him an everpresent awareness of the patient as a whole organism and contributing to his unusual diagnostic acumen and clinical judgment. To his high intelligence, excellent professional training and experience there was added a keen sensitiveness and intuitive understanding, together with a warmth of feeling and a depth of sympathy for those who suffer and are in distress, which is an essential part of the true physician. He was never too tired or too pressed for time to give generously of himself either to his patients or to his associates.

Doctor DuBois was born in Liberty, Indiana, and following graduation from Wabash College entered the Rush Medical College of the University of Chicago, where he was a member of Phi Beta Kappa and of Alpha Omega Alpha. Prior to specializing in neurology and psychiatry and joining the medical staff of Silver Hill in 1937, he was Professor of Anatomy; was active in the development of Connecticut's mental health program; was a past chairman of the Committee on Mental Health of the Connecticut State Medical Society, and at the time of his death was Chairman of the Board of Mental Health of the State of Connecticut. He was the author of many articles in the fields of neurology and psychiatry and was particularly interested in the problems of emotional adjustment in childhood and adolescence. Some of his papers dealing with the developmental

stages of the individual have been widely used for reference in schools and mental health groups.

Doctor DuBois was also active in his contributions to his community. In New Canaan he had served on the Board of Trustees at the Country School and was a member of St. Mark's Episcopal Church.

He was a diplomate of the American Board of Psychiatry and Neurology; a fellow of the American Medical Association, the American College of Physicians and the American Psychiatric Association, and a member of the American Neurological Association. He was an associate attending neurologist of the Vanderbilt Clinic of the Columbia-Presbyterian Medical Center; consultant to the department of psychiatry, Greenwich Hospital, Greenwich, Conn.; and consultant to the department of psychiatry and neurology of the Norwalk Hospital in Norwalk, Conn.

With the recurrence of his malignant disease last spring and his certain knowledge that he was in its terminal stage, Frank DuBois faced death with inspiring courage, and, in spite of physical torture, for weeks and months without complaint, his only concern was for his family, his patients, and his friends. The classic words which Mark Antony spoke would seem applicable to Frank Dubois:

His life was gentle, and the elements
So mix'd in him that Nature might stand up
And say to all the world "This was a man!"

Doctor DuBois is survived by his wife, Maurine Tompkins DuBois, his two sons, Arthur L., and Franklin S. DuBois, Jr., his parents, Mr. and Mrs. Smith DuBois of Liberty, Indiana, a sister, Miss Charlotte DuBois of Austin, Texas, and two grandchildren.

William B. Terhune, M.D.

THE ADOLF MEYER LECTURE CHILDHOOD MOURNING AND ITS IMPLICATIONS FOR PSYCHIATRY¹

JOHN BOWLBY, M.D.²

INTRODUCTION

For half a century or more there has existed a school of thought that has believed that experiences of infancy and childhood play a large part in determining whether or not an individual grows up prone to develop psychiatric illness. To the growth of this school Adolf Meyer made a great contribution. Insisting that the psychiatric patient is a human being and that his disturbed thought, feeling and behaviour must be seen in the context of the environment in which he is living and has lived, Adolf Meyer bade us pay attention to all the complex details of the patient's life history as possible clues to his illness. "The most valuable determining feature is, as a rule, the *form of evolution* of the [symptom] complex, the time and duration and circumstances of its development." Though I find no evidence that Adolf Meyer was greatly interested in experiences of earliest childhood, they lie plainly within his field of vision and are indeed a logical extension of his work.

Over the years, the belief that experiences of early childhood are of much consequence for the development of psychiatric illness has grown in strength. Nevertheless, the basic hypothesis has always been a subject of sharp controversy. Some have contended that the hypothesis is mistaken—that psychiatric illness has its roots elsewhere than in early childhood; whilst those who believe the hypothesis to be fruitful are still at sixes and sevens regarding precisely what experiences are relevant. Much of the controversy arises from the difficulty of conducting satisfactory research in this area—a difficulty turning largely on the long gap in time between the events thought to be of consequence and the onset of the de-

clared illness. For the science of psychopathology, therefore, the problem posed is how best to explore the area in order to reach firmer ground. My plan in this lecture is to give an account of recent developments in one line of investigation, that which has set out to understand the effect on personality development of loss of maternal care in early childhood.

In the past 20 years much evidence has accumulated that points to a causal relationship between loss of maternal care in the early years and disturbed personality development(7). Many common deviations seem to follow an experience of this kind—from delinquent character formation to a personality prone to anxiety states and depressive illness. Although there are some psychiatrists who still challenge this general conclusion, a more usual attitude is to accept that there is probably something in it and to ask for more information. A particular request has been for an hypothesis which can provide a plausible explanation of how it is that the ill effects attributed to separation and deprivation come to follow such experiences. Since it is to an attempt to fill this gap that I have been devoting myself in recent years, my plan is to present a sketch of where the evidence seems to be leading.

In judging my thesis I must ask you to bear in mind that the enquiry does not follow the usual practice of psychiatric research which starts with a more or less defined clinical syndrome and attempts then to delineate the underlying pathology. Instead, it starts with a class of experience, loss of mother figure in infancy and early childhood, and attempts thence to trace the psychological and psychopathological processes that commonly result. In physiological medicine a shift of this kind in research orientation has occurred long since. In studies, for example, of the pathology of chronic infection of the lungs, the investi-

¹ Read at the 117th annual meeting of the American Psychiatric Association, Chicago, Ill., May 8-12, 1961.

² Tavistock Child Development Research Unit, 2 Beaumont St., London, W. 1, Eng.

gator is no longer likely to start with a group of cases all showing chronic infection and attempt to discover the infective agent or agents that are at work. It is more likely he will start with a specified agent, perhaps tubercle or actinomycosis or some newly identified virus, in order to study the physiological and physiopathological processes to which it gives rise. In so doing he may discover many things which are not immediately relevant to chronic infective pulmonary conditions. Not only may he throw light on certain acute infections and sub-clinical conditions, but he is almost sure to discover that infections of other organs besides lungs are the work of the pathogenic organism he has selected for study. No longer is his centre of interest a particular clinical syndrome: it has become instead the manifold sequelae of a particular pathogenic agent.

The pathogenic agent the effects of which I shall be discussing is loss of mother figure during the period between about 6 months and 6 years of age. During the early months of life the infant is learning to discriminate a particular figure, usually his mother, and is developing a strong liking to be in her company. After about 6 months he shows his preferences in unmistakable fashion (55). Throughout the latter half of his first year and during the whole of his second and third he is closely attached to his mother figure, which means that he is content in her company and distressed in her absence. Even momentary separations often lead him to protest and longer ones always do. After the third birthday the strength of the attachment commonly diminishes, though for some further years it remains strong. From about his first birthday onwards other figures also, for example father or grandmother, may become important to him so that his attachment is not confined to a single figure. Nevertheless, there is usually a well-marked preference for some one person. In the light of phylogeny it is likely that the instinctual bonds that tie human young to a mother figure are built on the same general pattern as in other mammalian species (9, 30, 52).

The majority of children suffer little disruption of this primary attachment in their early years. They live with their mother

figure and, during the relatively brief periods when she is absent, are cared for by a familiar subordinate figure. On the other hand a minority does experience disruptions. Their mother may desert or die; they may be left in hospital or institution; they may be handed from one mother figure to another. Disruptions may be long or short, single or repeated. The experiences that belong under the general heading of maternal deprivation are thus multifarious and no one investigation can study them all. If, therefore, effective research is to be done, for each project the experience to be studied must be fairly narrowly defined.

As regards research strategies, the investigator has a choice (2). An obvious possibility is to examine a sample of older children and adults who had the experience in their early years with a comparable sample who did not have the experience. Although brilliantly adopted by Goldfarb (29), this strategy has many practical difficulties. The principle ones are locating a suitable sample, selecting and examining appropriate controls, and finding reliable instruments to measure the features of personality that are expected to show differences. An alternative approach is to study the child's responses at the time of and in the period immediately subsequent to the experience. After spending several not very productive years following the first strategy, it is the second on which my research group has concentrated during most of the past decade. It has been much more rewarding.

SEPARATION FROM MOTHER AND CHILDHOOD MOURNING

The basic data with which we have been concerned are observations of the behaviour of healthy children of a defined age, namely in their second and third years, undergoing a defined experience, namely stays of limited duration in residential nurseries or hospital wards and there cared for in traditional ways. This means that the child is removed from the care of his mother figure and all subordinate figures and also from his familiar environment and is cared for instead in a strange place by a succession of unfamiliar people. Further data are derived from observations of his behaviour in his home during the months after his return and

from reports of it from his parents. Thanks to the work of James Robertson and Christoph Heinicke we have now a considerable body of observations, some of which have been published (8, 31, 49, 50, 51). Because observations by a number of other workers (3, 14, 15, 34, 48, 54, 56), record substantially similar sequences of response, we feel fairly confident of the common patterns.

In the setting described a child of 15 to 30 months who has had a reasonably secure relationship to his mother and has not previously been parted from her will commonly show a predictable sequence of behaviour. This can be broken into 3 phases according to what attitude to his mother is dominant. We have described them as phases of Protest, Despair and Detachment.³ At first with tears and anger he demands his mother back and seems hopeful he will succeed in getting her. This phase of Protest may last several days. Later he becomes quieter, but to the discerning eye it is clear that as much as ever he remains preoccupied with his absent mother and still yearns for her return; but his hopes have faded and he is in the phase of Despair. Often these 2 phases alternate: hope turns to despair and despair to renewed hope. Eventually, however, a greater change occurs. He seems to forget his mother so that when she comes for him he remains curiously uninterested in her, and may seem even not to recognise her. This is the phase of Detachment. In each of these phases the child is prone to tantrums and episodes of destructive behaviour, often of a disquietingly violent kind.

The child's behaviour on return home depends on the phase reached during the period of separation. Usually for a while he is unresponsive and undemanding; to what degree and for how long turns on the length of the separation and the frequency of visits. For example, when he has been away unvisited for a few weeks or months and so has reached the early stages of detachment, it is likely that unresponsiveness will persist from an hour to a day or more. When at length it breaks the intense ambiv-

alence of his feelings for his mother is made manifest. There is a storm of feeling, intense clinging and, whenever his mother leaves him, even for a moment, acute anxiety and rage. Thenceforward, for weeks or months his mother may be subjected to impatient demands for her presence and angry reproaches when she has been absent. When, however, he has been away for a period of more than 6 months or when separations have been repeated, so that he has reached an advanced stage of detachment, there is danger that he may remain detached and so never recover his affection for his parents.⁴

Now in interpreting these data and in relating them to psychopathology a key concept is that of mourning. There is, indeed, good reason to believe that the sequence of responses described—Protest, Despair and Detachment—is a sequence that, in one variant or another, is characteristic of all forms of mourning. Following unexpected loss there seems always to be a phase of protest during which the bereaved person is striving, either in actuality or in thought and feeling, to recover the lost object and is reproaching it for desertion. During this and the succeeding phase of despair, feelings are ambivalent while mood and action vary from an immediate expectancy expressed in an angry demand for the object's return to a despair expressed in subdued pining—or even not expressed at all. Though alternating hope and despair may continue for a long time, at length there develops some measure of emotional detachment from the object lost. After having undergone disorganisation in the phase of Despair, behaviour in this phase becomes reorganised on the basis of the object's permanent absence. Though this picture of healthy mourning is not altogether familiar to psychiatrists, evidence that it is a true one seems compelling (12).

⁴ Many variables influence the child's behaviour during and after separation and this makes a brief schematic exposition difficult. The description given applies especially to the behaviour of children who are unvisited and are cared for by nurses or others who have little insight or sympathy for his fretting. It seems likely that free visiting and more insightful care can mitigate the processes described, but there is as yet little reliable information about this.

³ In certain earlier papers the term "Denial" was used to denote the third phase. It has many disadvantages, however, and has been abandoned.

If this view is correct, the responses of young children on removal to hospital or institution must be regarded simply as variants of basic mourning processes. Irrespective of age, it seems, the same kind of responses occur and in the same sequence. Like adults, infants and young children who have lost a loved object experience grief and go through periods of mourning (11). There appear to be only 2, inter-related differences. One is that in the young the time scale is abbreviated, though much less so than has sometimes been thought. The other, in which lies the significance for psychiatry, is that in childhood the processes leading to detachment are very apt to develop prematurely, inasmuch as they coincide with and mask strong residual yearning for and anger with the lost object, both of which persist, ready for expression, at an unconscious level. Because of this premature onset of detachment, the mourning processes of childhood habitually take a course that in older children and adults is regarded as pathological.

Once we recognise that the separation of a young child from his loved mother figure commonly precipitates processes of mourning of a pathological sort, we are able to relate our findings to those of many other enquiries. On the one hand are the findings of workers who have taken the grief of adults as a starting point for a study of psychopathology (18, 38, 42). On the other are those of the more numerous investigators who have followed the traditional pattern of psychiatric research, that starts with a sick patient and tries to discern what have been the preceding events of causal significance, and who have advanced the hypothesis that loss of loved object is in some way pathogenic.

Enquiries that have pointed to loss of loved object as probably pathogenic are of several kinds. First, there are the very numerous studies, of which Freud's *Mourning and Melancholia* is the prototype, that relate a psychiatric syndrome of relatively acute onset, such as anxiety state, depressive illness or hysteria, to a more or less recent bereavement, and postulate that the clinical picture is to be understood as the result of mourning having taken a pathological course. Next are the studies, almost equally

numerous, that relate a psychiatric syndrome of more chronic degree, such as a tendency to episodic depression or a difficulty in experiencing feelings, to a loss that occurred in the patient's adolescence or earlier childhood. Thirdly, there is the extensive psychoanalytic literature that seeks to relate a proneness towards psychiatric illness in later life with some failure of psychic development in early childhood. Fourthly, there is a steadily accumulating series of papers that show a raised incidence of childhood bereavement in the lives of those who subsequently develop psychiatric illness; and, finally, the striking observation that individuals are apt to become mentally ill at an age which appears to be determined by an episode in their childhood when they suffered the loss of a parent—the so-called anniversary reactions.

It is not possible in a single lecture to discuss systematically the relevance of the evidence derived from each of these sources. This I am attempting to do in a series of detailed papers in course of publication. The most that can be done now is to draw on a few typical studies from each field (but excluding anniversary reactions) and to indicate briefly how these findings appear to fit together. Since, however, the whole thesis turns on the nature of the processes of mourning and especially those present in the first phase, it is necessary to give them further attention.

URGES TO RECOVER AND TO REPROACH LOST OBJECT: THEIR ROLE IN PSYCHOPATHOLOGY

Now I wish to draw your attention to anger as an immediate, common and perhaps invariable response to loss. Instead of anger indicating that mourning is running a pathological course—a view suggested by Freud and rather commonly held—evidence makes it clear that anger, including anger with the lost object, is an integral part of the grief reaction. The function of this anger appears to be to add punch to the strenuous efforts both to recover the lost object and to dissuade it from deserting again that are the hallmarks of the first phase of mourning. Since this phase has not only been given little attention hitherto but appears crucial for an understanding of

psychopathology, it is necessary to explore it more fully.

Because in cases of death an angry effort to recover the lost object is so obviously futile there has been a tendency to regard it as itself pathological. I believe this to be profoundly mistaken. So far from being pathological, the evidence suggests that the overt expression of this powerful urge, unrealistic and hopeless though it may be, is a necessary condition for mourning to run a healthy course. Only after every effort has been made to recover the lost object, it seems, is the individual in a mood to admit defeat and to orient himself afresh to a world from which the loved object is accepted as irretrievably missing. Protest, including an angry demand for the object's return and reproach against it for deserting, is as much a part of the *adult's* response to loss, especially a sudden loss, as of the young child's.

This may seem puzzling. How comes it that such demands and reproaches should be made even when the object is so plainly beyond recall? Why such gross realism? There is I believe a good answer: it stems from evolution theory.

In the first place, a review of the behavioural responses to loss that are shown by infra-human species—birds, lower mammals and primates—suggests that these responses have ancient biological roots. Though not well recorded, such information as is available shows that many if not all the features described for humans—*anxiety and protest, despair and disorganisation, detachment and reorganisation*—are the rule also in many lower species.⁵

In the second place, it is not difficult to see why these responses should have been evolved. In the wild to lose contact with the immediate family group is extremely dangerous, especially for the young. It is, therefore, in the interests of both individual

safety and species reproduction that there should be strong bonds tying together the members of a family or of an extended family; and this requires that every separation, however brief, should be responded to by an immediate, automatic and strong effort both to recover the family, especially the member to whom attachment is closest, and to discourage that member from going away again. For this reason, it is suggested, the inherited determinants of behaviour (often termed *instinctual*) have evolved in such a way that the standard responses to loss of a loved object are always urges first to recover it and then to scold it. If, however, the urges to recover and scold are automatic responses built into the organism, it follows that they will come into action in response to *any* and *every* loss and without discriminating between those that are really retrievable and those, statistically rare, that are not. It is an hypothesis of this kind, I believe, that explains why a bereaved person commonly experiences a compelling urge to recover the object even when he knows the attempt to be hopeless and to reproach it even when he knows reproach to be irrational.

If then neither the futile effort to recover the lost object nor angry reproaches against it for deserting are signs of pathology, in what ways, we may ask, is pathological mourning distinguished from healthy? Examination of the evidence suggests that one of the main characteristics of pathological mourning is nothing less than an inability to express overtly these urges to recover and scold the lost object, with all the yearning for and anger with the deserting object that they entail. Instead of its overt expression, which though stormy and fruitless leads on to a healthy outcome, the urges to recover and reproach with all their ambivalence of feeling have become split off and repressed. Thenceforward, they have continued as active systems within the personality but, unable to find overt and direct expression, have come to influence feeling and behaviour in strange and distorted ways; hence many forms of character disturbance and neurotic illness.

Let me give a brief illustration of one such form, drawn from a case reported by Helene Deutsch (16).

⁵ Evidence is reviewed by Bowlby (12) and Pollock (47). To give an example quoted by Pollock: A male chimpanzee who had lost his mate is recorded to have made repeated efforts to arouse her. He yelled with rage and at times expressed his anger by snatching at the short hairs of his head. Later there was crying and mourning. As time wore on he became more closely attached to his keeper and more angry than he had been hitherto when the keeper left him.

When he came for analysis in his early thirties, this man was without apparent neurotic difficulties. The clinical picture, however, was one of a wooden and affectionless character. Helene Deutsch describes how "he showed complete blocking of affect without the slightest insight . . . He had no love relationships, no friendships, no real interests of any sort. To all kinds of experience he showed the same dull and apathetic reaction. There was no endeavour and no disappointment . . . There were no reactions of grief at the loss of individuals near to him, no unfriendly feelings and no aggressive impulses." How did this barren and crippled personality develop? In the light of an hypothesis regarding childhood mourning, the history together with material stemming from analysis enable us to construct a plausible account.

First, history: when he was 5-years-old his mother had died and it was related that he had reacted to her loss without any feeling. Thenceforward, moreover, he had retained no recollection of any events prior to her death. Secondly, material from analysis: he described how through several years of later childhood he used to leave his bedroom door open "in the hope that a large dog would come to him, be very kind to him, and fulfil all his wishes." Associated with this fantasy was a vivid childhood memory of a bitch which had left her puppies alone and helpless when she had died shortly after their birth. Although in this fantasy the hidden longing for his lost mother seems plainly evident, it is not expressed in a simple direct way. Instead, all memories of his mother had disappeared from consciousness and, insofar as any conscious affects towards her could be discerned, they were hostile.

To explain the course of development in this case the hypothesis I am advancing (and one that is not very different from Helene Deutsch's) is that, following his mother's death, instead of there being a full expression of his desire for his mother's return and anger at her desertion, his mourning had moved on precipitately to a condition of detachment. In so doing the yearning and the anger had become locked inside him, potentially active but shut off from the world, and only the remainder of his personality had been left free for further development. As a result he grew up gravely impoverished. If this hypothesis is valid, the task of treatment is to help the patient to recover his latent longing for his lost mother and his latent anger with her for deserting him, in other words to return to the first phase of mourning with all its ambivalence of feeling which at the time of the loss had either been

omitted or scamped. The experience of many analysts, well illustrated in a paper by Root (53), suggests that it is in fact only in this way that such a person can be restored to a life of feeling and attachment.

Strong support for this hypothesis comes from our observations of young children separated from their mothers and unvisited, especially from what we know of the early stages of detachment that follow protest and despair. Once the separated child has entered the phase of detachment he seems no longer preoccupied with his missing mother and instead to have adapted satisfactorily in his new surroundings. When his mother comes to fetch him, so far from greeting her he seems hardly to know her and, so far from clinging to her, remains remote and unresponsive; it is a condition that most mothers find distressing and incomprehensible. Provided the separation has not lasted too long, however, it is reversible, and it is in what happens after reversal that special interest lies.

After the child has been back with his mother a few hours or a few days, the detached behaviour is replaced not only by all the old attachment but by attachment of greatly heightened intensity. From this it is clear that during detachment the ties binding him to his mother have not quietly faded, as is suggested by Anna Freud (20),⁶ nor has there been a simple forgetting. On the contrary, the data strongly suggest that during the phase of detachment the responses that bind the child to his mother and lead him to strive to recover her are subject to a defensive process. In some way they are removed from consciousness, but remain latent and ready to become active again, at high intensity, when circumstances change.⁷ This means that in infants and young children the experience of separation habitually initiates defensive processes which lead to yearning for the lost object

⁶ In an earlier publication (14), however, Anna Freud adopted a viewpoint similar to that taken here.

⁷ The change of circumstance required varies with the stage to which detachment has progressed. When the child is still in the early phases, renewed attachment usually follows reunion with his mother: when he is in an advanced stage analytic treatment is likely to be required.

and reproach for its desertion both to become unconscious. Another way of stating it is that, in early childhood, loss is responded to by processes of mourning that habitually take a course that in adults is deemed pathological.

The question that now arises is whether the defensive processes that are so striking following loss in childhood are different in kind from what is seen in healthy mourning or whether they occur in healthy mourning also but with some difference of form or timing. Evidence suggests that they do occur⁽¹²⁾, but that in the healthy process their onset is delayed. As a result the urges to recover the lost object and to reproach it have time enough for expression so that, through repeated failure, they are gradually relinquished or, in terms of learning theory, extinguished. What appears to happen in childhood (and in the pathological mourning of later years), on the other hand, is that the development of defensive processes is accelerated. As a result, the urges to recover and to reproach the lost object have no chance to be extinguished and instead persist, with consequences that are serious.

Let us return briefly to apply these ideas to Helene Deutsch's patient. Following his mother's death when he was 5, it seems, both longing and anger had disappeared from his conscious self. The fantasy of the visit from the dog shows, however, that they persisted nonetheless at an unconscious level. This and evidence from other cases suggests that, although immobilised, both his love and his anger had remained directed towards the recovery of his dead mother. Thus, locked in the service of a hopeless cause, they had been lost to the developing personality. With loss of mother had gone loss also of his feeling life.

Two common technical terms are in use to denote the processes at work: fixation and repression. Unconsciously the child remains fixated on the lost mother: his urges to recover and to reproach her, and the ambivalent emotions connected with them, have undergone repression.

Another defensive process, closely related to and alternative to repression, also occurs following loss. This is "splitting of the ego." In such cases one part of the personality, secret but conscious, denies that the object

is really lost and maintains, instead, either that there is still communication with it or that it will soon be recovered; whilst simultaneously another part of the personality shares with friends and relatives the knowledge that the object is irretrievably lost. Incompatible though they be, the two parts may co-exist over many years. As in the case of repression, ego splits lead also to psychiatric illness.

Why in some cases the part still yearning to recover the lost object should be conscious and in others it should be unconscious is unclear. So too are the conditions which lead some bereaved children to develop satisfactorily whilst others do not.⁸ What seems certain, however, is that the precipitate onset of the defensive processes, repression or splitting, with the resulting fixation, is initiated much more readily in childhood than in more mature years. In this fact lies a main explanation, I suggest, of why and how it is that experiences of loss in early childhood lead to faulty personality development and proneness to psychiatric illness.

The hypothesis I am advancing, therefore, is that in the young child the experience of separation from mother figure is especially apt to evoke psychological processes of a kind that are as crucial for psychopathology as are inflammation and its resulting scar tissue to physiopathology. This does not mean that a crippling of personality is the inevitable result; but it does mean that, as in the case, say, of rheumatic fever, scar tissue is all too often formed which in later life leads to more or less severe dysfunction. The processes in question, it seems, are pathological variants of those that characterise healthy mourning.

Although this is a theoretical position that is closely akin to many others already in the field, it appears nonetheless to be different from them. Its strength lies in relating the pathological responses with which we are confronted in older patients to responses to loss that are actually to be observed in early childhood, thereby providing a more solid link between psychiatric conditions of later life and childhood experience. Let us turn

⁸ This is a problem that Josephine Hilgard is studying (33).

now to compare this formulation with some of its predecessors.

TWO TRADITIONS IN PSYCHOANALYTIC THEORISING

During this century a number of psychoanalysts and psychiatrists have sought to relate psychiatric illness, loss of a loved object, pathological mourning and childhood experience. Almost all have taken as their starting point the sick patient.

It is more than 60 years since Freud first adumbrated the idea that both hysteria and melancholia are manifestations of pathological mourning following more or less recent bereavement(25), and more than 40 years since in *Mourning and Melancholia* he advanced the hypothesis in a systematic way(21). Since then there have been a host of other studies all of which in different ways support it; recently this literature has been ably reviewed by Parkes(46). Clinical experience and a reading of the evidence leaves little doubt of the truth of the main proposition—that much psychiatric illness is an expression of pathological mourning—or that such illness includes many cases of anxiety state, depressive illness and hysteria, and also more than one kind of character disorder. Plainly there has been discovered here a large and important field; for it to be explored fully much further work is required.

Controversy begins when we come to consider why some individuals and not others respond to loss in these pathological ways: and it is amongst hypotheses that seek to account for the origin of such differential responsiveness that the one I am advancing belongs.

An hypothesis that has influenced all later workers with a psychological orientation was outlined by Abraham(1). As a result of analysing several melancholic patients, he came to the conclusion that "in the last resort melancholic depression is derived from disagreeable experiences in the childhood of the patient." He therefore postulated that, during their childhood, melancholics have suffered from what he termed a "primal parathymia." In these passages, however, Abraham never uses the words grief and mourning; nor is it clear that he recognised that for the young child

the experience of losing mother (or of losing her love) is in very truth a bereavement.

Since then, a number of other psychoanalysts in trying to trace the childhood roots of depressive illness and of personalities prone to develop it have drawn attention to unhappy experiences in the early years of their patients' lives. Except in the tradition of theorising initiated by Melanie Klein, however, few have conceptualised the experiences in terms of bereavement and pathological mourning. Nevertheless, when we come to study the experiences to which they refer, it seems evident that this is the frame of reference that best fits them. I will give as examples 3 patients described in the literature.

In 1936 Gerö reported 2 patients suffering from depression. One of them, he concluded, had been "starved of love" as a child; the other had been sent to a residential nursery and had only returned home when he was 3. Each showed intense ambivalence towards any object that was loved, a condition which, Gerö believed, could be traced to the early experience. In the second case, he speaks of both a fixation on the mother and an inability to forgive her for the separation. Edith Jacobson in her extensive writing on the psychopathology of depression draws regularly on a female patient, Peggy, whose analysis she describes in 2 papers(36, 37). On referral, Peggy, aged 24, was in a state of severe depression with suicidal impulses and depersonalisation; these symptoms had been precipitated by a loss, actually the loss of her lover. The childhood experience on which Edith Jacobson places major emphasis occurred when Peggy was 3½ years old. At this time her mother went to hospital to have a new baby, whilst she and her father stayed with the maternal grandmother. Quarrels developed and father departed. "The child was left alone, disappointed by her father and eagerly awaiting her mother's return. However, when the mother did return it was with the baby." Peggy recalled feeling at this time "This was not my mother, it was a different person," (an experience that we know is not uncommon in young children who have been separated from their mothers for a few weeks). It was soon after this, Edith Jacobson believed, that "the little girl broke down in her first deep depression."

Now it may be questioned both whether the experiences in these patients' early

childhoods were accurately recalled and also whether the analysts were right in attributing to them so much significance for their patients' emotional development. But, if we accept as I am inclined to do both the validity of the experiences and their significance, I believe the concept of pathological mourning to be the one best fitted to describe both how the patient responded at the time and also to relate the experience of childhood to the psychiatric illness of adult life. Neither author utilises this concept, however. Instead both use concepts such as "disappointment" and "disillusionment" which appear to have a different significance.

Several other analysts, whilst in greater or less degree alive to the pathogenic role of such experiences in childhood, also do not identify the child's response to loss with mourning. One is Fairbairn (19). A second is Stengel who, in his studies of compulsive wandering (58, 59, 60), draws special attention to the urge to recover the lost object. A third is the present writer in his earlier work (6, 7). Others are Anna Freud (20) and Rene Spitz (57), both of whom, by disputing the notion that infants and young children mourn, have ruled out as a possibility the hypothesis that neurotic and psychotic character developments are sometimes the result of mourning in childhood having taken a pathological course.

A main reason why the child's response to loss is so often not identified with mourning appears to be a tradition that confines the concept "mourning" to processes that have a healthy outcome. Although this usage, like any other, is legitimate, it has one grave disadvantage: logically it becomes impossible to discuss, as such, any variants of mourning that may seem pathological. The consequent difficulties are illustrated by Helene Deutsch already quoted (16). In her discussion there is firm recognition both of the central place of childhood loss in the production of symptoms and character deviations and also of a defence mechanism which, following loss, may lead to an absence of affect. Nevertheless, although she relates this mechanism to mourning, it is represented more as an alternative to than as a pathological variant of mourning. Whilst at first sight this distinction may appear one merely of terminol-

ogy, it is of more significance. For to regard the defensive process following childhood loss as an alternative to mourning is to miss both that defensive processes of similar kinds but of lesser degree and later onset enter also into healthy mourning, and also that what is pathological is not so much the defensive processes themselves as their intensity and the prematurity of their onset.

Similarly, although Freud was on the one hand deeply interested in the pathogenic role of mourning and on the other, especially in his later years, was also aware of the pathogenic role of childhood loss, he seems nonetheless never to have put his finger on childhood mourning and its disposition to take a pathological course as concepts which link these 2 sets of ideas together. This is well illustrated in his discussion of the splitting of the ego in the defensive process, to which he was giving special attention at the end of his life (23).

In one of his papers (22), Freud describes 2 patients in whom an ego split had followed loss of father.

In the analysis of two young men, I learnt that each of them—one in his second and the other in his tenth year—had refused to acknowledge the death of his father . . . and yet neither of them had developed a psychosis. A very important piece of reality had thus been denied by the ego . . . [But] it was only one current of their mental processes that had not acknowledged the father's death; there was another that was fully aware of the fact; the one which was consistent with reality [namely that the father was dead] stood alongside the one which accorded with a wish [that the father should still be living] (22).

In this and related papers, however, Freud does not relate his discovery of such splits in the ego to the pathology of mourning in general nor to childhood mourning in particular. He did recognise them, nevertheless, as the not uncommon sequelae of bereavements in early life. "I suspect," he remarks when discussing his findings, "that similar occurrences are by no means rare in childhood." Recent statistical studies, we shall see, show that his suspicion was well-founded.

Thus a reading of the literature shows that, despite attributing much pathogenic

significance to loss of a parent and to loss of love, in the main tradition of psycho-analytic theorising the origin of pathological mourning and of the consequent psychiatric illness in the adult is not connected with the disposition for processes of mourning to take a pathological course when they occur following a loss in infancy and early childhood.

I believe it to have been a major contribution of Melanie Klein(39, 40) to have made this connection. Infants and young children mourn and go through phases of depression, she maintains, and their modes of responding at such times are determinants of the way that in later life they will respond to further loss. Certain methods of defence, she believes, are to be understood as "directed against the 'pining' for the lost object." In these respects my approach is identical with hers. Differences arise, however, over the particular experiences that are thought to be of importance, the age at which they are thought to occur, and the nature and origin of anxiety and aggression.

The experiences of loss which Melanie Klein has suggested are pathogenic, all belong to the first year of life and are mostly connected with feeding and weaning. Aggression is regarded as an expression of the death instinct, and anxiety the result of its projection. None of this I find convincing. In the first place the evidence she advances regarding the overwhelming importance of the first year and of weaning is, on scrutiny, far from impressive(11). In the second, her hypotheses regarding aggression and anxiety are not easy to fit into a framework of biological theory(10). It is, I believe, because so many find the elaborations with which Melanie Klein has surrounded the hypothesis regarding the role of childhood mourning implausible that the hypothesis itself remains neglected. This is a pity.

My position therefore is that, although I do not regard the details of Melanie Klein's theory of the depressive position as a satisfactory way of explaining why individuals develop in such diverse ways that some respond to later loss with healthy mourning whilst others do so with one or another form of pathological mourning, I nonetheless hold her theory to contain the

seeds of a very productive way of ordering the data. The alternative elaborations which I believe the evidence favours are that the most significant object that can be lost is not the breast but the mother herself (and sometimes the father), that the vulnerable period is not confined to the first year but extends over a number of years of childhood (as Freud, 24, held), and that loss of a parent gives rise not only to primary separation anxiety and grief but to processes of mourning in which aggression, the function of which is to achieve reunion, plays a major part. Whilst sticking closely to the data, this formulation has the additional merit of fitting readily into biological theory.

Substantial though the differences are between Melanie Klein's standpoint and mine, the area of agreement is also substantial. Both hold as a main hypothesis that processes of mourning occurring in these early years are more apt than when they occur later in life to take a pathological course and so to leave the individual thenceforward more prone than others to respond to further loss in a similar way. The version of this theory that I am now advancing appears to be consistent with much of the clinical material published in the literature and already referred to. This includes Freud's cases of splits in the ego, Stengel's cases of compulsive wandering, the depressive patients described by Abraham, Gerö and Edith Jacobson, and the patients with character defects described by Helene Deutsch, Melanie Klein, Fairbairn and the present writer. It is also consistent with the numerous studies which have appeared in the past 2 decades which show that the incidence of childhood loss in the lives of patients suffering from psychiatric illness and character defect is significantly higher than in a random sample of the population.

INCIDENCE OF CHILDHOOD LOSS IN PSYCHIATRIC PATIENTS AND DELINQUENTS

In a valuable critique of a dozen statistical papers on this topic available to him at the time of writing in 1958, Gregory remarks that "various selective factors, small samples, and lack of standardization in the recording of data render relatively few comparisons justifiable either with each other" or with data from controls. He points out

the many pitfalls in making such studies, some of which may exaggerate differences between psychiatric patients and controls but some of which mask them. Some of the reported data he re-works. After this careful and disinterested examination his conclusions carry weight. The incidence of loss of one or other parent in childhood, he holds, is almost certainly higher in the case of psychiatric patients than it is in the general population.

In considering and comparing the results of the various studies it must be borne in mind that each is concerned not only with a different kind of patient but often with a different kind of loss and with losses occurring at different times in the patient's life. This makes for confusion. A special problem arises in connection with age at loss, both because it is so central to our thesis and also because so many different age criteria have been employed. Some authors take a specified age in the late 'teens or even early twenties and count the losses that occurred at any time before it: others count losses occurring before a specified age somewhere in the early 'teens. There are a few, however, who divide the years of childhood into a number of age periods, and give the incidence of loss for each separately; for example, for the first 5 years of life, for the second 5 years, and so on.

Scrutiny of these data makes it clear that only the last type of study is satisfactory, because differences of incidence between patients and controls which are clearcut and significant during one 5-year period can

be largely or completely hidden when losses occurring during 2 or more such periods are summated. It is this undifferentiated way of presenting data that almost certainly accounts for some of the negative findings reported (e.g., 35).

Another cause of real difference being masked is the elimination of cases on the score of the inadequacy of data regarding childhood history, since, as Gregory points out, the incidence of early loss in such cases is likely to be raised.

For presentation in this lecture I have selected 4 studies which appear to have been carefully executed and to give reasonably trustworthy results (see Tables 1, 2 and 3). One of them is concerned with psychiatric inpatients, two with psychiatric outpatients, and one with persistent delinquents. In the first 3 studies the indices of loss are the loss of mother and father separately and by death only; in the fourth, the delinquents, the index used is loss of either or both parents and for any of a number of reasons, e.g., death, desertion, separation, divorce.

Barry was one of the first to be interested in this field and has published a number of studies. That of 1949(4) compares a sample of nearly 1,700 patients who were aged 40 years and under when admitted to a U. S. mental hospital with a control series of subjects derived from life insurance tables; 60% of the patient group were diagnosed as dementia praecox. Figure 1 shows the incidence for the 2 groups of loss of mother through death by the age of the

TABLE III
Incidence of First Loss of One or Both Parents (all Causes) by Age of Subject at Time of Loss
(From Glueck and Glueck 1950)

Age at Loss Years	Incidence of Loss		Difference	P
	Delinquent	Non-Delinquent		
	%	%	%	
0-4	34	16	18.0 ± 2.67	.001
5-9	17	10.5	6.5 ± 2.16	.01
10-14	9	7	2.0 ± 1.64	NS

patient at the time of loss. It will be seen that the incidence among patients both in the first 5 years of life and in the second 5 years is about double that of the controls ;

in both cases the difference is statistically significant ($P < .01$). In the age period 10-14, incidence for the patients remains raised but is no longer significant.

INCIDENCE OF LOSS BY DEATH

MOTHER

FATHER

Fig #1

Fig #2

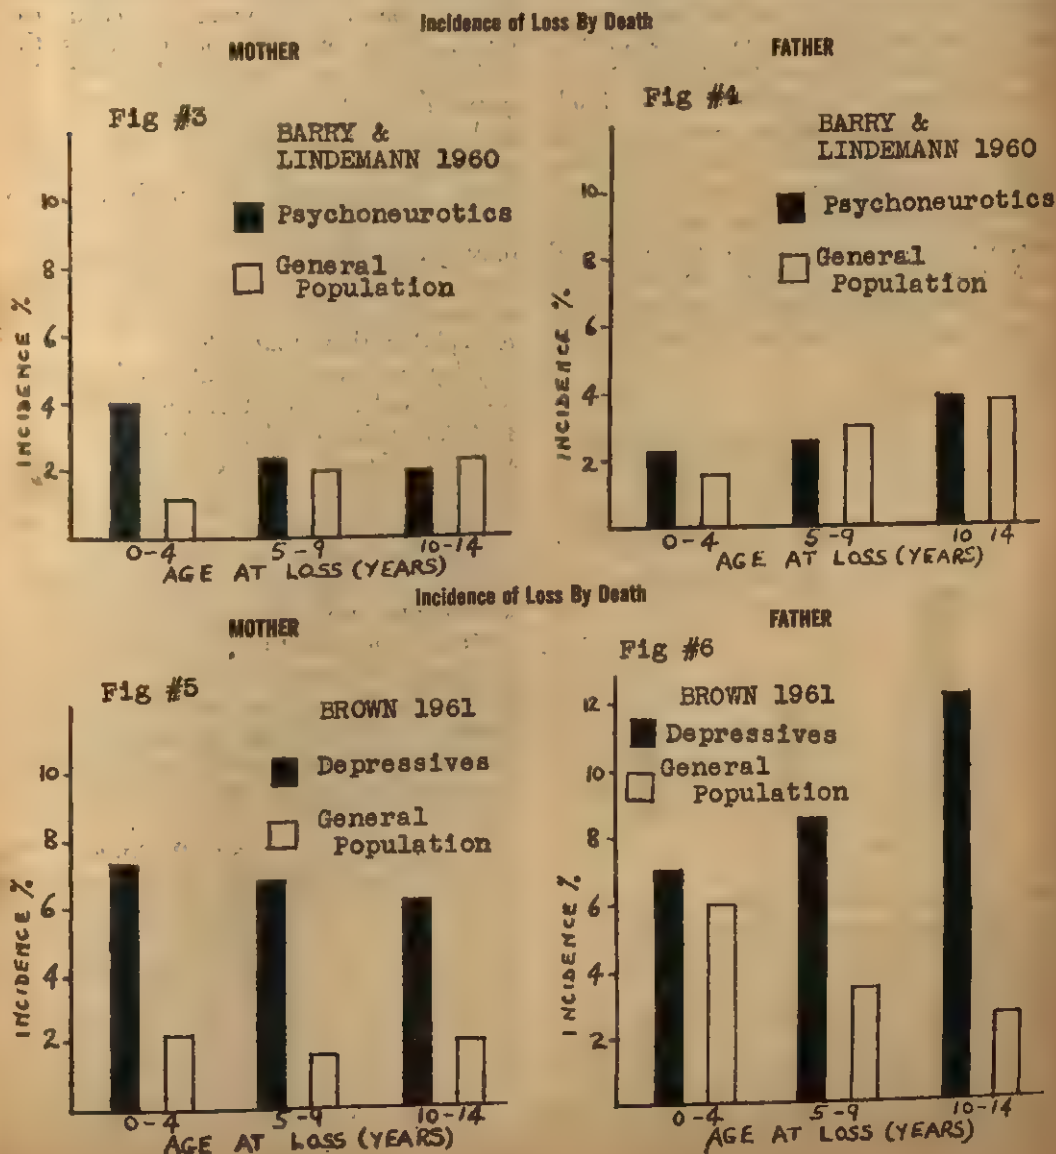

Figure 2 shows the incidence for the 2 groups of loss of father by death. Here again the incidence for the patient group is higher than for the controls, but this time it is less evident. Only in the 5-9 year age-period does the difference reach statistical significance ($P < .05$).

Last year Barry published another rather similar study(5). This time he investigated a group of nearly 1000 outpatients with diagnosis either psychoneurosis or psychosomatic illness. For this group the differences in parental death rates are much less marked than for the inpatients. Nevertheless Figure 3 shows that loss of mother in

the first 5 years remains significantly raised ($P < .01$). Incidence of loss of mother at older ages, however, and loss of father during each of the age periods (Figure 4) are not very different in the patient group than in the controls.

Very recently an English psychiatrist, Felix Brown, whose theoretical position regarding the significance of childhood loss is similar to my own, presented figures in which incidence of parental loss in a group of over 200 depressive patients was compared with that of the general population as derived from the census of 1921(13). Figure 5 gives his findings for loss of mother

by death. The high incidence of loss during all 3 age periods is striking and significant ($P < .01$ for the younger age groups and $< .02$ for the 10-14 age group). Incidence of loss of father by death (Figure 6) is also high during each age period, though, because of the war of 1914-18, during the youngest age period it is high also for the controls each delinquent was paired with a periods incidence of loss for the depressives is above that for the controls to a significant degree ($P < .01$).

The fourth study which I have selected concerns not psychiatric patients but 500 persistently delinquent boys in their early teens. This is perhaps the best of the many studies carried out by the Gluecks (27). For controls each delinquent was paired with a non-delinquent boy matched for age, intelligence, national origin and residence (mostly in poor neighbourhoods). In this study the criteria of parental loss are extensive and include loss not only by death but by divorce, separation, desertion and prolonged absence due to illness or imprisonment. Since no breakdown is given as to which parent was lost, Figure 7 shows

the incidence of loss of either or both. Here, we are again struck by the raised incidence of loss during the first 5 years of the delinquents' lives. In fact in each of the two younger age periods the incidence of loss for the delinquents is significantly higher than for the controls ($P < .01$).

Apart from one British study of psychiatric outpatients published by Norton (44),

where virtually no significant difference in incidence of loss is found, the other studies available (e.g., 45, 61, 62, 41) all tell the same story. What is so striking is the consistency with which a raised incidence of loss is reported for the first 5 years of life. It is a finding that strongly supports the view that it is these early years that are the most critical.

Which, if any, of these years show a specially high incidence of parent loss, however, is more difficult to discern because most investigators do no more than group their cases into losses occurring within the whole of a 5-year period. Only 2 reports, both by Barry, give figures for each year separately. In one, that on inpatients, the incidence of loss of mother by death remains above the actuarial expectations for each year until about the eighth, after which it drops to the expected level. In the other, on outpatients, the incidence tends to be raised during each of the first 3 years only. These findings, it will be seen, do nothing to support the view held by some analysts that the first year of life is more critical than those that follow.

When we come to evaluate the figures for loss of mother and father respectively we find that incidence of loss of mother in the patient groups is more consistently above the expected rate than is incidence of loss of father (Tables 1 & 2). This is shown dramatically when we consider the age period 0-4 years. In each of the 3 studies I have presented, the incidence of loss of mother by death in the first 5 years is raised in significant degree (in each case $P < .01$). In none of them is the incidence of loss of father by death raised significantly. This strongly supports the view that in regard to the early years it is loss of mother that tells.

As regards later years, 2 studies (the first of Barry's and the one by Brown) show a raised incidence of loss by death both of mother and of father in the age period 5-9. Brown's study, but neither of the other 2, shows a similar finding for the 10-14 year age period. These findings suggest that during the long period from 5 to 14 years, which covers latency and early adolescence, loss of father by death is of about equal importance to loss of mother

by death as an antecedent of psychiatric illness.

Of the various psychiatric syndromes which, it has been suggested are associated with parental loss in the early years, Gregory concludes that the evidence is most substantial in the case of personalities prone to delinquent and psychopathic behaviour. I believe this conclusion well-founded.⁹ Evidence in regard to patients with depressive symptoms, however, especially those who are actively suicidal is strong also. In addition to the findings of Brown (which were not available to Gregory), there have been a number of reports linking early loss of a parent, both by death and other causes, with suicide or attempted suicide. Among the first to make this connection was Zilboorg (64); and there is a recent statistical study by Walton (63). Although Walton's figures go some way to support Zilboorg's hypothesis, unfortunately the form in which he presents them is such that they cannot be compared with those already given.

In considering the relevance of the statistical data to my argument certain doubts are likely to be in your minds. In the first place, it will be remarked, we must beware of the fallacy *post hoc ergo propter hoc*. In the second, even if we are right in claiming a causal relationship between early loss and subsequent illness, it does not follow that it is always mediated by means of the pathological processes that have been described earlier. There are, indeed, two other sorts of process which almost certainly give rise to pathology in some cases. One is the process of identification with parents, which is an integral part of healthy development but which often leads to difficulties after one of them has died.¹⁰ The other sort are

evoked by the surviving parent, widow or widower, whose attitude towards the child may change and become pathogenic.

There is another difficulty that the hypothesis must meet. Even if it is true that there is a raised incidence of death of parents in the childhood histories of individuals prone later to develop certain types of personality and certain forms of illness, its absolute incidence is nevertheless low. How, it will be asked, are the other cases to be accounted for? There is more than one possible explanation.

In the first place, in order to base my argument on firm evidence, I have deliberately restricted most of the discussion of statistical data to the incidence of parental death. When other causes of parental loss in the early years are included, as they are in the Glueck's study, the percentage of cases affected is greatly increased. Furthermore, for many of the cases in which there has been no episode of actual separation in space of child from parent, there is often evidence that there has nonetheless been separation of another and more or less serious kind. Rejection, loss of love (perhaps on advent of a new baby or on account of mother's depression), alienation from one parent by the other, and similar situations, all have as a common factor loss by the child of a parent to love and to attach himself to. If the concept of loss of object is extended to cover loss of love these cases no longer constitute exceptions.

It seems unlikely, however, that such an extension would cover all cases falling within the psychiatric syndromes concerned. If this proves to be so some other explanation for those not accounted for by the present hypothesis needs to be sought. Perhaps on closer examination the clinical picture of such cases will prove to be different in material degree from those that are accounted for. Alternatively, the clinical conditions may prove to be essentially similar but the pathological processes in cases not accounted for to have been initiated by events of a different kind. Until these and other possibilities have been explored problems will remain. Since, however, there is rarely a simple relationship between syndrome, pathological process and pathogenic experience, the problems are no

⁹ A recent study by Earle & Earle (17) shows that in a sample of 1423 psychiatric patients under the age of 60, examined by the authors in outpatient clinics, mental hospitals and general hospitals, 100 (7%) had suffered severe maternal deprivation before the age of 6 years, due either to death of mother (48) or to separations lasting 6 months or longer (52). Amongst the deprived the incidence of sociopathic personality was 27%; amongst the remainder 2.9% ($P < .01$).

¹⁰ Psychiatric disturbance in which identification with a lost parent plays a significant part has for long been a subject of study by analysts. It is particularly clear in anniversary reactions (32).

different from those which occur constantly in other fields of medical research.

CONCLUSION

It is probably true that by far the most research in the field of psychiatry today still starts with an end-product, a sick patient, and seeks to unravel the sequence of events, psychological and physiological, that appear to have led to his becoming sick. This results in many suggestive hypotheses but, like any single method of enquiry, has its limitations. One of the hallmarks of an advancing science is exploitation of as many methods as can be devised. When in physiological medicine research was expanded to include the systematic investigation of one or another probable pathogen and its effects, a great harvest of knowledge was garnered. Adolf Meyer, we know, looked forward to the day when the same would be possible in psychiatry. "When we know better what to look out for," he wrote in 1903, "we may undertake studies of *developing* abnormalities which are not insanity yet, and follow them out so as to accumulate material of *actual observation* on which to build a solid theory"

Because of its practical and scientific implications, the study of responses to loss of mother figure in the early years might have appealed to Adolf Meyer. On the practical side he might have been attracted by the vision of our becoming able to develop measures to prevent at least some forms of mental ill-health. On the scientific side he would, no doubt, have valued the opportunities that stem from the identification of an experience of childhood that is probably pathogenic, can be clearly defined, and the effects of which on the developing personality can be systematically studied by direct observation.

There are, of course, many other experiences of childhood besides loss that there is good reason to believe also contribute to the development of disturbed personality and psychiatric illness. Examples are the child's experience of one or another of the various sorts of parental attitude that have long been the subject of concern and therapeutic endeavour in child psychiatric clinics. For each the research task is, first, to define the experience, secondly, to locate a sample

of cases in which it is occurring so that its effects on psychological development may be studied, and, finally, to relate the processes that are found to be set in train by it to processes present in patients with declared illness. The consequences of such an expansion of research are far reaching. It is my hope that the illustration of its adoption that has been given will encourage others to try the same route.

The author is much indebted to James Robertson for the observations on which he has drawn and to him, Robert Hinde, and Anthony Ambrose for discussions in which ideas were clarified. The enquiry was undertaken as part of the work of the Tavistock Child Development Research Unit, which is supported by the National Health Service and by grants from the Foundations Fund for Research in Psychiatry and the Ford Foundation, to which our thanks are due.

A PRELIMINARY REPORT ON THE CONTINUED POST-HOSPITAL USE OF TRANQUILIZING DRUGS¹

ROBERT J. WOLFF, PH.D., AND DORIS M. COLACINO, R.N.²

For a number of years the ataractic drugs have played an important role not only in the treatment of the mental illnesses, but also in helping patients to maintain themselves after hospitalization (1, 2). The Minnesota Follow-up Study, a demonstration project sponsored by the National Institute of Mental Health and administered by the State Department of Public Welfare, was designed to investigate the personal and societal factors that effect the post-hospital adjustment of patients. In addition to information collected during hospitalization, follow-up data were collected on all patients at regular intervals after discharge by means of an interview with the patient, an interview with a relative or "significant other," and ratings made by the interviewer. In addition to information giving a measure of the "success" the patient has in maintaining himself in the community, a number of questions were asked to determine the use of tranquilizing medication during the post-hospital period. This paper is a preliminary report on some of the findings, covering the first 6 months after discharge of a sample of almost 150 patients.

The sample consisted of all patients released from one of the Minnesota state hospitals (Moose Lake State Hospital) returning to reside in St. Louis County. About half the population of St. Louis County, in northern Minnesota, lives in Duluth, the other half lives in smaller towns and rural areas. Medical facilities in St. Louis County, and especially in the city of Duluth, are probably a little better than average for a city of 100,000.

One of the purposes of the Minnesota Follow-up Study was to mobilize available resources in the County. Individuals and agencies in the County have been extreme-

ly helpful in providing assistance where needed: it can be said that for the majority of patients in the sample, it would have been possible to contact either a general physician or a psychiatrist, and it seems highly unlikely that anyone would have gone without medication because they could not afford to do so; public and other assistance was available for all patients in the sample.

The return rate for this sample was high: approximately 25% of patients returned to the hospital within 6 months. The information from the follow-up interviews concerns, therefore, only those who managed to maintain themselves at least 6 months. There are indications in this study that 2 important factors contributed to early re-hospitalization. One was the "well-being" of the patient himself, how well he was functioning in the community, how well he came up to expectations in the community, *etc.* The other factor was the "tolerance of deviance" of relatives and significant others: the more tolerant the relatives were of deviant behavior in general, and the behavior of the patient in particular, the less chance he had to be rehospitalized. Probably as a result of the importance of this second factor it was also found that patients who after their release lived in a foster or boarding home, with unrelated others, were rehospitalized significantly less frequently than those who lived with their spouse, parents, or relatives. Other factors, such as age, I.Q., psychiatric diagnosis, clinical prognosis made in the hospital, and certain psychological factors were shown to have a very tentative effect on subsequent rehospitalization.

The Minnesota Follow-up Study staff was active with approximately half of the sample in an intensive casework relationship. Considerable efforts were made, for instance, with this "experimental" group to get them to see their doctors. Although the staff members would not, of course, actually urge the patient to continue to take his

¹ The Minnesota Follow-up Study, of which this investigation was a part, is administered by the Minnesota Department of Public Welfare, and supported by a grant (OM-29(C2)) of the National Institute of Mental Health.

² 120 N. 4th Ave. W., Duluth 2, Minn.

medication, or take it more regularly, nevertheless the patient would be urged to follow his doctor's prescriptions as closely as possible. In the majority of cases, too, the staff members would be in close contact with the physician, so that he had significantly more information on patients in the experimental group than on patients in the "control" group.

Evidence collected suggests that the activities of the staff with the experimental group, including not only the work with the physician but with a great variety of agencies in the community, was "successful" in that the return rate for this group was significantly reduced, compared to the control group. At the same time it seems that, although the staff members were moderately successful in preventing rehospitalization in a number of cases, no significant improvement could be obtained in the "well-being" of patients in the experimental group. This does not mean, however, that generally the group interviewed 6 months after discharge (the third interview) was not doing better than the group interviewed immediately upon discharge: at the time of the third interview a significant selection had already taken place so that on an average the patients who were able to maintain themselves in the community at least 6 months were doing slightly better than the average of all

patients interviewed immediately upon discharge.

RESULTS

Almost 75% of all patients interviewed immediately upon discharge report that the State hospital had prescribed tranquilizing drugs for the post-hospital period. A complete breakdown of medication and dosage is not available as yet, but from preliminary analysis it appears that the majority of discharged patients continue on chlorpromazine, on dosages of from 100 to 400 mgm. (4). The great majority of interviewees reported that they were taking the medicine: and the great majority reported that they were taking it regularly (Table 1).

As time goes on, and as the sample is reduced by the rehospitalization of those who cannot maintain themselves in the community, the percentage of patients reporting that someone is prescribing tranquilizing drugs for them is increasing, although the percentage reporting that they are actually taking the medicine and taking it regularly is decreasing! It seems unlikely that the significant and progressive reduction of the percentage who do take tranquilizing medicine regularly is a result of a significant increase in their "well-being." From other measures it appears that the increase in "well-being" is slight, so that the consider-

TABLE 1

Percentage of Discharged Patients who Indicate They Continue on a Tranquilizing Drug Regime, Immediately After Discharge and 6 Months after Discharge

	IMMEDIATELY AFTER DISCHARGE	SIX MONTHS AFTER DISCHARGE
Patients report that tranquilizing drug is prescribed:	74.4% (N = 145)	82.6% * 1 (N = 109)
Patients report they are taking their medication:	83.6% (N = 122)	65.8% ***2 (N = 73)
Patients report they are taking medication "regularly":	92.0% (N = 115)	82.9% * (N = 63)

1 The attrition in the size of the sample interviewed 6 months after discharge is caused by rehospitalization of some patients, as well as by patients moving away from the area.

2 Not included are a number of patients who did not respond.

* difference significant at .05.

*** difference significant at .001 or better.

able decrease in the proportion of people continuing to take their medication must probably be attributed to other factors (Table 2).

the post-hospital period, and though apparently many community physicians also prescribe such treatment for discharged patients, the results, from this study at least, do

TABLE 2
The "Total Well-Being Score"* 8 Months After Discharge

Patients continuing to take tranquilizing medicine regularly, at least 3 times a day :	3.62 (N = 29)
Patients continuing to take tranquilizing medicine, but irregularly, or infrequently :	3.59 (N = 42)
Patients not continuing on tranquilizing medication :	3.85 (N = 37) NS

* The "Total Well-being Score" is a compound rating, based on 5 scales, each giving an evaluation of a patient's functioning in a particular area of behavior (non-instrumental performance, instrumental performance, fulfillment of role expectations, function impairment, subjective well-being). Low score signifies "better" adjustment, more normal behavior.

Hospital records for the past several years show that with the introduction of the ataractic drugs there was a significant increase in the discharge rate. Tranquilizing medicine administered in the hospital has made patients more manageable, made it possible to discharge more patients and to discharge them earlier. Even though there is obviously a tendency on the part of the hospital physician to prescribe tranquilizing drugs for

not show the effectiveness of such medication after discharge. There is no significant difference between patients who do and those who do not continue on tranquilizers, either in terms of their rehospitalization or of their observable behavior ("adjustment"). A tentative conclusion, based on information obtained in this study, may be that tranquilizers "help" the patient in the hospital, speed his discharge, but that after

discharge psychological and societal rehabilitation apparently play a greater role than drugs in furthering his recovery(3).

It is interesting to note that where within the first month of discharge (first interview) almost half of the patients indicate that they receive their tranquilizing medicine on a prescription given by the hospital, even after 6 months there is still a significant number (17%) who report that they receive their medication from a hospital prescription (Table 3).

It must be remembered that this information is obtained from the responses of the patients, and that there is always an element of unreliability in this information. However, the follow-up interviews were designed to provide a maximum reliability by eliminating as much as possible ambiguous or anxiety-provoking questions. There is no reason to assume that the 17% of the sample who responded that even after 6 months they received their medication on a hospital prescription spoke untruthfully. The staff was well aware that there are pharmacists who will continue to refill prescriptions written a long time ago. There is a change also in the proportion of patients who report that they receive prescriptions from physicians in the community (immediately upon discharge, 1/3 of all patients interviewed, of those interviewed 6 months after discharge, almost 3/4 so reported). It is interesting to note also that patients in the "experimental" group showed a higher percentage receiving a prescription from a psychiatrist or a psychiatric clinic; a somewhat larger percentage of the "control" group reports that they receive their prescriptions from general physicians.

Among those who report that they are no longer taking the medication prescribed by the hospital, an ever increasing proportion reports that this is because there is "no need" (Table 4). This may mean either that

a physician has so advised or that they have themselves so determined. The latter seems more likely as only about 50% indicate that they have seen a physician in the recent past. Corroborating evidence can be found in the increasing percentage of patients who report that they do take tranquilizing medicine, but not "regularly." These include those who take medicine "occasionally," "for a day at a time," "when needed," "when I remember to," etc. This suggests that patients who do continue to use tranquilizing medicines after their discharge from the hospital do so less and less regularly as time goes on, that more of them feel they can be the judge as to when and how often they should take their medicine.

The information collected suggests that patients in the experimental group, who received considerably more follow-up care, tend to rely on their own judgments less, and to follow the advice of their physicians more (Table 5). It should be stressed again that the follow-up care provided for these patients was mostly in terms of "keeping in touch with" them. The professional workers (social workers, a psychiatrically oriented public health nurse, and a psychologist) made a point of seeing patients on a regular basis and directing them to individuals and agencies in the community who were able to provide the needed services.

SUMMARY

A sample of patients discharged from a state hospital was interviewed at regular intervals; this preliminary report includes information obtained at the 6 months' follow-up. In addition to an evaluation of observed, objective well-being ("adjustment"), information was obtained from the patients concerning their continued use of tranquilizing medicine.

1. A very large percentage of patients are discharged with the recommendation that

TABLE 4
Percentage of Patients no Longer on Tranquilizing Drugs who Indicate There is "No Need"

	IMMEDIATELY UPON DISCHARGE	SIX MONTHS AFTER DISCHARGE
"If you are no longer taking medicine, why not?":		
"No need":	38.5% (N = 10)	53.7% NS (N = 22)

TABLE 5
Percentage of Patients who Continue to Take Tranquilizing Medicine "regularly" in the "Experimental" and "Control" Groups

	SIX MONTHS AFTER DISCHARGE
Continue "regularly" :	
Experimental group :	88.6%
Control group :	78.0% NS
*Both groups combined :	82.9%
	(N = 115)

they continue on a regime of tranquilizing medication.

2. As time goes on, the percentage of patients who follow this advice decreases significantly, and even those who report that they continue to use the tranquilizing drugs become less "regular" in their medical regime.

3. In this study no conclusive evidence could be found that patients remaining on a tranquilizing drug did any "better" than those who did not: there is no significant difference in the rehospitalization rate, nor is there a significant difference in their observable functioning in the community. Therefore where the tranquilizing drugs have shown their effectiveness in the hospital, for the post-hospital period other means than purely medical treatment seem more effective in promoting recovery.

4. Many patients seek the advice of a physician in the community, under whose care they continue their tranquilizing drug regime. Nevertheless, even after 6 months, there is a significant number who apparently

can get their original prescriptions refilled for a long time without the supervision of a local physician.

5. The study was able to show that with relatively little effort on the part of a few professional workers with discharged patients, a closer cooperation with local individuals and agencies (physicians, psychiatrists, clinic, etc.) can be obtained, showing as a result a higher percentage of patients who continued to take prescribed drugs as well as a higher percentage who take them "regularly."

EXPERIENCE WITH PROMAZINE

N. H. RATHOD, M.B., B.S., D.P.M.¹

It may be said with some justification that the phenothiazine group of drugs plays an important part in the treatment of psychiatric disorders, this being specially so in psychiatric hospitals where chronically disturbed patients are treated. Promazine or Sparine is one of such phenothiazine derivatives. Its range and degree of effectiveness are still under discussion and opinions vary.

Pharmacology of promazine is only meagerly known, but its activity appears to be similar in range and location to chlorpromazine though weaker(15). Animal experiments suggest that neuronal activity is inverse to local A.T.P. concentration. Like chlorpromazine, but to a lesser degree, promazine increased A.T.P. concentration in thalamic and hypothalamic areas of cats, thus suggesting that it decreases neuronal activity in these areas(12). Also like chlorpromazine it subdues excited animals but unlike it, it does not cause sedation(4). Repeated clinical reports about its usefulness in states of excitement, and tension in patients and lack of drowsiness during its administration lend support to these experimental findings. Its ability to reduce anxiety and psychomotor activity is attributed to its inhibitory action on subcortical levels. It is also suggested that the drug blocks reflex patterns originating in the reticular formation. It raises the pain threshold blocks alerting reaction to pain in rabbits, and also causes emotional detachment to pain. This may account for the beneficial effects of the drug in organic pain syndromes(17).

Results of promazine therapy in psychiatric practice vary a good deal. However, literature suggests that the drug can be used effectively in various disorders where chlorpromazine is indicated. Studies of its application in the treatment of neuroses are scarce and are so far not encouraging(25). Given intravenously it is said to be very effective in the treatment of withdrawal symptoms of alcoholic intoxication.

Toxic Effects : With experience growing, undesirable side effects of the drug are coming to light. Transient orthostatic hypotension, dizziness, generalized tremors are not uncommon, and occasional G.I. tract irritation, dermatitis and hyperpyrexia have been observed.

Vascular collapse terminating into death though rare has been observed (Sainz) and on the basis of experience with nearly 2,500 patients, Shea, *et al.*, think it inadvisable to administer the drug to patients with impending vascular collapse. We have seen an aged man with arteriosclerosis and hypertensive heart disease go into an irreversible cardiovascular collapse and die while receiving promazine in 300-400 mg. a day orally. Peripheral arterial thrombosis has been reported in two patients following I.V. administration of the drug(20).

Toxic confusional state has been known to occur(16). Pai(21) has reported development of a picture resembling pseudo-bulbar palsy and Parkinsonism combined in a man receiving only 25 mg. t.d.s. of promazine for less than a week. Hare(13) has reported development of an unusual dystonic syndrome in a patient receiving the drug. A small proportion of patients receiving over 1,000 mg. of the drug orally per day are known to develop grand mal seizures(16, 3, 26, 18). Experience of Donald McLean, *et al.*(19), suggests that the risk of G.M. attacks is greater in patients with a history of convulsions(19). Shea, *et al.*(26), advise prophylactic use of anticonvulsant drugs where there is history or likelihood of reduced excitability threshold of CNS. We have not come across clinical evidence of epileptic seizures in our series. Agranulocytosis, though rare does occur. We have analysed available data on 8 reported cases. In summary, it appears that occurrence of agranulocytosis has little relationship to method of administration, dosage, and duration of treatment. It occurs usually in patients over 50 (6 out of 8 cases—ages of two others not known) and women seem to be favoured. Mortality is rather high despite treatment (3 out of 6 women and

¹ Senior Hospital Medical Offices, Warlingham Park Hospital, Warlingham, Surrey, England.

none out of two men).

Although some of the complications of promazine therapy are serious, they are not common. On the other hand the drug is relatively free of complications like Parkinsonism, jaundice and distressing drowsiness which occur with other phenothiazines and some of them even with Rauwolfia alkaloids.

We present here data on our experience with promazine at Cane Hill Hospital. They are derived from a triple blind trial with chronically disturbed female patients; and from the review of clinical records of all the male patients treated with this drug. This latter part of data is presented under the heading "Uncontrolled Trial."

TRIPLE BLIND TRIAL

Population : The trial started with 25 patients but 4 were omitted because they required change of treatment.

These 21 patients suffered from schizophrenia of various types. The diagnosis of schizophrenia was based on the criteria enumerated in *Textbook of Psychiatry* by Meyer Gross, Slaters and Roth, 1954.

In the past, 8 of these patients had received one or more of the following physical treatments : E.C.T., leucotomy, deep insulin and lately all of them had prolonged trials (not less than 12/12) with chlorpromazine or Pacatal. No treatment had brought about any lasting or marked improvement.

The age range was from 37 to 67 years. None had been in this hospital for less than 8 years and all had been in the same experimental ward for more than a year. In all, 4 or more of the following, dominated their clinical picture : 1. Physical or verbal aggressiveness ; 2. Uncooperativeness or obvious negativeness ; 3. Social withdrawal including mutism ; 4. Evidence of excitable or impulsive behaviour ; 5. Mannerisms ; 6. Hallucination, visual or oral ; 7. Delusions ; 8. Urinary incontinence.

Environment : The patients formed part of the total population of 90-100 patients in a close ward. Occupational therapy was provided in and out of the ward. Patients enjoyed freedom to go out of the ward if their clinical condition made this possible, but these 21 patients in the trial did not leave the hospital premises, and only on rare occasions did they have visitors. The ward was

run by one ward sister, and 2-3 nurses on each shift. The hospital works 2 day shifts. The sisters of the ward and the doctor in charge remained unchanged for at least a year before and during the trial.

Method : The environment of the ward was as constant as possible. All medication and physical treatments were withdrawn for about 3-4 weeks before the trial. During it any other medication or physical treatment was withheld except very occasional administration of sedatives (sod. amytal or paraldehyde) at nights. Before the trial the patients were told they were going to have a new treatment. The possible side effects and toxic effects of the drug were explained to the nursing staff ; they were also told that the trial would be blind and that their accurate observations were very important. It may be said that the staff has had good experience with drug trials. A few days before the trial patients were examined by the ward doctor who selected them if they satisfied the criteria mentioned. Once these patients were seen, the ward sisters and the doctor selected the 25 patients for whom the ward sisters pleaded treatment. These patients presented no signs of any physical illness.

Administration : The drug was administered orally in 300 mg. dose daily. The trial was divided into two parts ; the first part lasted 5-6 weeks, the second 10-12 weeks. For the first 3 weeks the patients received placebo or active drug and for the next 3 weeks changed over to active drug or placebo ; the patient thus acted as his own control. During this part of the trial the identity of the medication was unknown to the doctor, the nursing staff and the patients. The pharmacist alone knew what the patient was getting. This period was followed by the second. Everyone concerned knew the patient was getting the active drug, the administration of which is summarized below.

Part 1 *		Part 2 **	
	3/52	3/52	10-12/52
Patient A	Active	Placebo	Active
Patient B	Placebo	Active	Active

* Identity of the Drug-Known only to the Pharmacist.

** Known to everyone concerned.

Records : The ward sisters and the doctors independently kept data on clinical condition and side effects. The ward sisters recorded, every week, the clinical condition of the patient on a specially devised item sheet with 28 items, each item rated on a 3-point scale. The doctor made notes on the clinical state before start of the trial, before change-over of the drug and at the end of the trial. We tried to interview the patients' visitors in order to get their opinions on the patients' condition; however, these were sporadic, so the idea was dropped.

Results : At the end of the trial it was found that none of the 21 patients showed any noticeable improvement. Some patients, however, did show some transient changes. An abusive, impulsive patient became less so. One patient emerged out of her depressed mood and became elated. One patient stopped picking hair from her scalp. Two patients became more co-operative. One became more agitated and started stripping herself. No side effects were observed but no regular pathological investigations were carried out.

UNCONTROLLED TRIAL

Our disappointing results with the controlled trial were indirectly responsible for the lack of enthusiasm for use of this drug on more female patients. But on the male side of the hospital the drug had been tried for quite a while before our trial began. We were aware of the various reasons why the drug did not prove effective on the female population, e.g., the patients were chronic and therapeutically rather discouraging; the dosage might not have been sufficient; the female patients might be more resistant than the male patients, etc. Therefore we set out to compare the results with the effects of this drug on male patients.

Population : The 45 male patients were divided into 2 groups on the basis of the duration of present attack of illness : Group A—24 patients with duration less than 15 months; Group B—21 patients with duration more than 15 months. Criteria for the selection of male patients cannot be given precisely because the trial was not a planned one. The main aim was to try the drug on various psychiatric disorders where it was claimed to be useful. Of the 21 pa-

tients in group B, 18 suffered from various types of schizophrenia (mainly paranoid) and their clinical picture was dominated by the following effects : hallucinations, mainly auditory; delusions, mainly persecutory; excitable or aggressive in behavior. The remaining two suffered from mania or hypomania and one from recurrent agitated depression. Of the 24 patients in Group A, 3 had been ill for 7 to 15 months and the other 21 had been ill for 1 to 6 months. Diagnostically they fell into the following groups : depression (endogenous)(3); mania or hypomania(19, 20, 29); schizophrenia(1, 6, 7, 8, 9); schizophrenia paranoid(11, 12, 18, 24, 27, 33, 34, 35, 37); schizophrenia catatonic(13); paranoid state(12, 21, 22). Only 4 of them had had any physical treatment in the past, and they were among the group who were ill for more than 7 months. The rest had had no other treatment for their present attack before starting promazine.

Environment : While the Group B patients had a more or less stable ward environment, the patients in Group A were shifted more often. Depending on their condition, they would either be in a closed ward with close supervision and provided with recreational and occupational therapy facilities, or they were in an open ward with better nursing, occupational and recreational facilities and a permissive atmosphere regarding their movements in and out of the ward.

Method : We collected all available data on the male patients who had been tried on promazine. They were collected under the following headings : Diagnosis; previous mental illness and its outcome; duration of present attack and its response to various treatments in the past; clinical condition before starting promazine; dosage and duration of promazine treatment; effects of promazine treatment; and 6 months follow-up after discharge from hospital.

Administration : In all there were 45 patients (male), who received promazine; 42 received the drug for 3 months to a year. It was administered orally, 300-500 mg. doses a day. There was no attempt to control the effects either by comparing it with placebo or with any other drugs. No other treatment accompanied promazine therapy except

night sedation (sod. amytal) when needed. In fact, we excluded those patients who received promazine and some other form of treatment, e. g., E.C.T.

Records : Weekly notes on Group A and monthly notes on Group B were maintained by the ward doctor.

Results : From the data we collected it became evident that as far as chronic patients (Group B) were concerned, there was no noticeable or lasting improvement. However, of 24 patients in Group A, 6 recovered from their present attack; 5 remained well during the follow-up period; one relapsed 3 months after discharge. One patient improved but not enough to warrant discharge. Below are some relevant points in the history and clinical state of the 6 patients in Group A.

Key to Histories : P.M.H.—Previous mental health; D.A.—Duration of recent attack; C.S.—Clinical state (main features); T.—Treatment; R.—Result; F.U.—Follow-up; D.—Diagnosis.

C.J.S. : aged 29. P.M.H.—no illness known. D.A.—1 year(?), C.S.—grandiose attitude and ideas, aural hallucinations ++. No insight. D.—schizophrenia. T.—promazine 100 mg. t.d.s. for 6 months. R.—markedly improved in all symptoms. F.U.—3 months later relapsed and re-admitted with grandiose and other ideas and delusions; ideas of influence and aural hallucinations.

C.R.P. : aged 31. P.M.H.—attack similar to present one in 1954; garrulous hallucinations +. D.—schizophrenia. T.—promazine 200 mg. t.d.s. for 5 months. R.—no hallucinations; co-operative, reliable kitchen worker, but facile and flat in expression. Still in hospital having promazine.

P.A.W. : aged 30. P.M.H.—sociable, cheerful, popular, similar attack 1954-1955. D.A.—1 week, C.S.—tense, suspicious, aggressive, paranoid delusions ++ not systematised, no insight. D.—paranoid schizophrenia. T.—promazine 200 mg. t.d.s. for 4 months. R.—symptom free. F.U.—keeping well, takes Sparine.

D.T. : aged 60. P.M.H.—always nervy, could not keep jobs. D.A.—6 months. C.S.—depressed, agitated, suspicious, quarrelsome. D.—endogenous depression. T.—treated with 6 E.C.T. without effect. Then promazine 50 mg. t.d.s. for 6 months. R.—symptom free. F.U.—working and keeping well.

E.R. : aged 63. P.M.H.—sociable, liked changing jobs, many attacks in the past similar to present one. C.S.—elated ++ impulsive, no

insight, flight of ideas ++, garrulous. D.—hypomania. T.—promazine 100 mg. t.d.s. for 3 months. R.—markedly improved but inclined to be elated and garrulous. Working and keeping well.

P.R. : aged 31. P.M.H.—poor social mixer, difficulty in holding jobs. D.A.—3 months. C.S.—hallucinated, ideas of influence, catatonic excitement. D.—catatonic schizophrenia. T.—promazine 200 mg. t.d.s. 3 months. R.—symptom-free. F.U.—2 slight relapses coinciding with stopping Sparine. Resumed Sparine; recovered; working well.

M.G. : aged 50. P.M.H.—friendly; inclined to be aggressive; attacks similar to present one in 1954 and 1957. D.A.—1 year. C.S.—aggressive and truculent, overactive, ideas of reference +. D.—paranoid psychosis. T.—promazine 150 mg. t.d.s. for 1 year. R.—no ideas of reference, not overactive, inclined to be hostile. F.U.—keeping very well on Sparine 50 mg. t.d.s.

DISCUSSION

Our experience with this drug in the treatment of disturbed patients suffering from schizophrenia is not encouraging. This is at variance with many other investigations. We hope that the reasons for this apparent discrepancy will become obvious in the following :

1. Objective procedures for the evaluation of treatment are rarely utilized. Among the 30 papers studied we found that Sibilo, *et al.* (27), were the only investigators who used statistical methods; it is interesting to note that the slight change noticed in their population was not significant. The possibility of this being due to chance could not be excluded.

2. Blind trial procedures utilising placebos are scarcely utilized. Sibilo, *et al.* (27), Simpson and Jesson (28) used this procedure and it is worth recording that none reported significant improvement with this drug.

3. Little attention appears to be paid to the environment in which the experiment is carried out (1, 2, 9, 10). S. M. K. Frain (30) describes environment of patients in some detail but unfortunately does not differentiate between the effect of environment from that of the drug.

4. There is virtual absence of data about ancilliary treatments; these can influence the results a good deal.

5. Follow-ups are rarely reported. This

we feel is specially important when clinical improvement is attributed to the drug. It is well known that initial good results prove fallacious if patients are followed up long enough.

ACUTE PORPHYRIA PROVOKED BY BARBITURATES GIVEN WITH ELECTROSHOCK THERAPY

JOSEPH MANN, M.D.¹

There is much literature on different aspects of porphyria and its manifestations; according to Remmer(1), Baumstark was the first who, in 1874, was able to prove the presence of porphyria in the urine of a patient.

Since this time numerous studies were published, and the classification of porphyria proposed many years ago by Gunther(2), has been widely used. Gunther's differentiation between porphyria congenita, acuta, and chronica, is somewhat conflicting; therefore, the classification of Watson(3): (a) photo-sensitive, (b) intermittent acute and (c) mixed, seems to be more realistic. As the name indicates, the intermittent acute form (the most common one) is characterized by individual attacks of longer or shorter duration with different periods of remission, during which the patient is free of symptoms. It is not the purpose of this paper to give a detailed classification and description of the variety of the clinical forms of porphyria, which are widely known in internal medicine and neurology. I would only like to mention 2 interesting cases which I could observe as a resident in internal medicine in 1956.

One is a 25-year-old white man, a Polish immigrant to the U.S.A., who had had a gastrectomy for peptic ulcer in 1952 and later suffered from "uncertain, unpleasant, colic-like cramps of the abdomen." All studies, except porphyria, were negative; and the same results were found in a 45-year-old, single, white woman whom I saw on two occasions with complaints of severe precordial pain and absolutely negative EKG studies. This lady also had high porphyrin values in her urine. Both of these cases were seen by consulting neuropsychiatrist and classified respectively as anxiety reaction and hysteria.

The psychological and neurological changes in a patient with porphyria have been described very thoroughly by Schmidt(4) in 1952, and one year later, Hare(5)

reported 2 cases of acute porphyria with mental symptoms (toxic confusional psychosis, and the second one, post-operative depression with pain and weakness suggestive of hysteria). In the same year, Olmstead(6) pointed out "the psychiatric syndrome is the common denominator of this disease, being present to some degree in all phases of the illness. Although it in itself is not diagnostic, the psychiatric aspects, plus severe abdominal complaints and the superimposition of neurological findings, should strongly point to the need for testing for abnormal amounts of porphyria in the urine."

Electroshock treatment for porphyria with psychotic symptoms was described by Lemere(7), who cured 2 patients with this treatment in 1954. The following is a description of my own case, in which a probably existing porphyria, masked under the appearance of hysteria, with depressive overlay in a basically schizoid individual, became manifest during the course of EST given with barbiturates as pre-medication. There is evidence that different drugs, especially barbiturates, are, at times, active in precipitating attacks of porphyria.²

M. L., a 21-year-old white girl, was admitted to the psychiatric ward of a private hospital on March 29, 1958, with the following chief complaints: nausea, vomiting, backpain, weakness and depression. Two weeks earlier, the patient underwent, in a different hospital, a pre-sacral neurectomy with D & C for severe primary dysmenorrhea, the history of which extended back to her menarche at age 13. Her periods had always been very irregular, associated with general malaise, and once (from the fall of 1957 to January of 1958) there had been an amenorrhea of 5 months duration. Following the gynecological operation the patient developed acute

² Waldenstroem(8) was able to demonstrate an attack of porphyria following the intake of barbiturates. He gave barbiturates to an individual who had never had previous attacks, but whose latent porphyria was discovered when his sister's manifested porphyria led to the study of other members of the family. After an intake of barbiturates, he developed acute porphyria.

¹ Chief of Admission Service, Ypsilanti State Hospital, Ypsilanti, Mich.

hysterical and psychotic (confused) episodes during the immediate anesthetic recovery period. She was discharged from the hospital and immediately the symptoms of emotional disturbance progressed in severity at home. The symptoms which precipitated hospitalization to the psychiatric unit were: withdrawal, with hysteric manifestations, such as rolling eyes and refusing to speak. In addition, the patient was suffering from insomnia and refused to eat.

Two days prior to her admission, medication was initiated by her family physician with meprobamate 400 mg. t.i.d., and she received some form of "supportive therapy." Further significant medical history included measles, chicken-pox and mumps in early childhood and a T & A at age 9. At 14 years the patient was injured in an accident while riding in a horse-drawn cart, resulting in a head contusion with unconsciousness for 2 hours. No doctor was called. The patient was the second youngest in a family of 5 children. The parents' marriage, despite the fact that her father was 20 years her mother's senior, was a stable one. The most significant relationship with the family was a rivalry with her younger sister, 16 at that time, who appeared to the patient to be "more beautiful and successful socially" than the patient. Our knowledge of the sister was limited, except for information that at the time of the patient's hospitalization the sister was illegitimately pregnant, and there were indications of a considerable degree of promiscuity on her part.

The patient had had no hetero- or homosexual experiences. Her ability to relate with her peers was impaired. She graduated from high school and was employed as a typist. On admission the patient was very anxious, apprehensive, whining and demanding that the therapist help her. The physical examination was essentially negative, showing only a slight enlargement of the thyroid gland, tachycardia 120 per minute and a milky discharge from the breast. Her abdomen was moderately tense, the postoperative scar slightly tender, and the patient was menstruating. The skin was dry and dehydrated, the physiological reflexes were hyperactive, but still within normal limits. Two chest x-rays were negative, and the skull examination did not reveal any erosions, or evidence of intracranial pressure. Sella turcica and basilar structures were reported as normal. An EKG obtained a few days later showed sinus tachycardia, marked muscle tremor and PR 0.18, QRS 0.08. Spinal puncture and subsequent evaluation were normal with no cells in fluid. Blood and liquor serology were negative. RBC was 4,180,000; WBC was 7500

with 65 segm.; 35 ly, Hb 78% equal to 11.7 gms., microhematocrit 38.

Due to symptoms of dehydration and refusal to eat, administration of parenteral fluids (glucose in NS.) was carried out. The patient was placed on amo- and secobarbital sodium 3 grains at h.s. for insomnia, and meprobamate was replaced by phenothiazine hydrochloride 50 mg., I.M. daily because the patient refused to take medication orally. This was also the reason that on April 2, she received her first EST as a treatment of choice. The preparation was seconal grains 1½, given to her the night before, and immediately prior to the ESTs, she received diacetylcholine chloride 20 mg. and thiamylal sodium 5 cc. I.V. In 2 subsequent days the patient received 2 additional treatments, and because the electrolytes showed low potassium levels, 3.4 (normal 4.1-5.6), she was placed on potassium chloride grams 1 q.i.d. on April 4, which she continued to take. An LE examination was negative, repeated blood studies were about the same. On April 6, the second urinalysis, when compared with the first one which was negative, showed 2 plus albumin with WBC 20-30 and rare erythrocytes. Following the third EST on April 4, the patient received, in addition, 5 more convulsive treatments, making a total of 8. No beneficial results were obtained from the course of ESTs and the patient felt increasingly miserable.

Quite by accident, a red color of the urine was observed, and the test for porphyria was positive on April 16. It was decided to stop ESTs immediately, phenobarbital, its derivatives and aspirin. The medication was changed to chlorpromazine 25 mg. q.i.d. and 25 mg. I.M., p.r.n., B-12 1000 micrograms I.M. and versenate 0.5 grams q.i.d. (April 18, which was doubled 2 days later). The porphyrine in the urine on April 17 was positive; on April 21, positive; and on 3 following examinations; April 25, April 28 and May 1, negative. All hysterical symptoms disappeared, and the patient started to walk around, to eat properly and to socialize with other patients. She was discharged as improved on May 2, 1958. Recent contact with her has confirmed her continued health and ability to work.

CONCLUSION

Porphyria in a patient can, under certain circumstances, especially when under barbiturates, produce symptoms of an emotional disorder, which do not respond to the psychiatrically oriented therapies, but must be treated medically. There is a possibility

that in many cases diagnosed primarily as "mental disorder," "hysteria" or other "emotional disturbance," a hidden factor of porphyria exists, which can be easily determined by laboratory testing. It is needless to state that this evaluation could be beneficial in the successful diagnosis and treatment of some patients now in mental hospitals.

CHILDREN OF SCHIZOPHRENIC PATIENTS: PRELIMINARY OBSERVATIONS ON EARLY DEVELOPMENT

DAVID E. SOBEL, M.D.¹

Several reports(1, 2) indicate that an extremely high percentage of newborns of 2 schizophrenic parents will show signs of emotional disorder in later life. We assumed that some of these newborns would show signs of emotional disorder in their infancy. A second assumption we made was that the behavior of their schizophrenic parents would be at least partially responsible for the emotional disorders anticipated in some of these infants. With these two preliminary assumptions in mind we chose to follow a small group of newborns of 2 schizophrenic parents from birth onwards. Our primary goal was to observe directly the parental behavior leading to the emotional disorders expected in some of the infants. We hoped that from such observations we might be able to identify specifically what in the behavior of a parent precipitates early emotional maldevelopment. Our two preliminary assumptions were supported by the data as it emerged. We felt that our data would be of additional interest in that: 1. To our knowledge no formal, direct observations on how schizophrenic parents care for their infants have been previously reported and 2. No study which goes in any detail into the early development of children with 2 schizophrenic parents has been previously reported. One reason that such data has not been reported must be due to the difficulty in locating and following newborns of 2 schizophrenic parents. The method we employed in finding our case material was as follows:

Pregnant women with the diagnosis of schizophrenia were located in 4 local New York State Department of Mental Hygiene after-care clinics and in 7 local state hospitals. These women were interviewed by the investigator to check the diagnosis. If the diagnosis of schizophrenia was confirmed, the putative fathers were located

and interviewed. Paternity was established on the basis of clear-cut statements by both mother and father. Cases in which promiscuity was suspected were excluded. Our criteria for the diagnosis of schizophrenia were very rigid. Pseudoneurotic schizophrenics were not included. Since we were looking for psychopathology in offspring as reported by Lewis, Kallman, *etc.*, we had to be certain that we were selecting the same kinds of parents as were selected by these authors. Each of the parents chosen had been hospitalized in either a state or Veterans Administration mental hospital on at least one occasion prior to our study. It took almost 2 years drawing on a population of approximately 65,000 hospital and after-care clinic patients to locate 8 cases in which we were certain that both expectant mother and father were schizophrenic.

After birth, each infant was observed in the neonatal period. Of the 8 cases followed, 4 infants (born to inpatients) then went to foster homes where they were followed with the permission of the various placement agencies. The remaining 4 infants (born to after-care clinic patients) went home to their original schizophrenic parents where they were then followed. This neat division in which 4 infants went to foster parents and 4 infants went to their schizophrenic parents was unplanned and was to prove quite useful to us. Monthly observations (occasionally more frequent) were made in the mother's or foster mother's home beginning in the third week of the infant's life. The observations were carried out by a psychiatrist trained in pediatrics, child psychiatry and psychoanalysis. The home visits were 1-3 hours in duration, varying with the circumstances in the home at the time of the particular visit. The investigator's effort was to fit his observations in the natural schedule of the family as much as possible. He would frequently arrive at times when feeding and bathing of the infant were likely to take place. A rou-

¹ Director, Family Study Unit, New York State Psychiatric Institute; Instructor, Department of Psychiatry, Columbia University College of Physicians and Surgeons, N. Y.

tine pediatric examination was often done which required the mother to undress and dress the child and thus to some degree interact with the infant. On occasion the schizophrenic mothers were observed in the Family Study Unit of the New York State Psychiatric Institute. The latter is an observation unit which consists of a kitchen, living room and combination nursery-playroom. The following is a report of our preliminary findings :

Three of the 4 newborns who went to their original schizophrenic parents developed clear-cut signs of emotional disorders in infancy. None of the 4 newborns of 2 schizophrenic parents who went to foster parents developed any such clear-cut signs of emotional disorder in their first 18 months of life. Since all 8 infants had a "common heredity for schizophrenia" and yet only the infants reared by schizophrenic mothers (3 of 4) showed clear-cut signs of early emotional disorder, the data supported our original assumption that the emotional maldevelopment observed in these infants was at least partially due to the behavior of their schizophrenic parents. What then in the parental behavior of the 3 schizophrenic mothers might have been responsible for the symptoms of emotional disorder observed in their infants? To answer this question we tried to determine how the parental behavior of these 3 schizophrenic mothers differed from the parental behavior of the foster parents and the fourth schizophrenic mother whose infants did not develop clear-cut signs of emotional disorder. Cases I, II and III consist of our observations on the parental behavior of the 3 schizophrenic mothers which led to disturbance in their infants and which stood out in striking contrast to our observations on the foster parents and the fourth schizophrenic mother. Case IV is a brief summary of relevant observations on the fourth schizophrenic mother. More detailed descriptions of the emotional maldevelopment of the infants are also included. The infant observations reported are those which stood out in clear contrast to our observations on the infants reared by the 4 non-schizophrenic mothers.

Case I. Mother : Mrs. Z. was a 25-year-old

negro woman. She had been hospitalized on two occasions prior to our study with a diagnosis of schizophrenia, catatonic type, with marked depressive features. Mrs. Z. was the only one of the 4 schizophrenic mothers followed who was resistive to any real cooperation with our study. She would frequently forget and/or break appointments. She was chronically depressed, withdrawn, "shy," and evasive. The striking features of her interaction with her infant were the following : She was consistently depressed and rarely if ever did she play with her infant. She engaged in very little sensory or motor stimulation of the baby. She showed no warmth in her attitude except for a slight smile when the observer made a pleasant remark about the baby. The mother responded to the infant's physical needs effectively and appeared to appropriately judge the baby's needs. The physical care Mrs. Z. gave to her infant was performed quite proficiently but with an absence of any "positive" feelings, i.e., the smiling, warmth and "playfulness," which so often accompanied the caretaking activities of the non-schizophrenic foster parents. Gradually the mother became even more depressed, agitated, withdrawn. She resisted hospitalization for a period of 4 months and finally admitted herself to a mental hospital when the infant was age 13 months.

Infant : Prior to the mother's hospitalization baby M.'s physical and emotional development were grossly deviant. Motor development was markedly retarded. Head raising was delayed. Baby M. (a girl) did not sit until 12 months of age. She was generally hypoactive and rarely smiled. Babbling and cooing were minimal. She appeared hypersensitive to sensory stimuli, and had frequent gastrointestinal upsets. She was very "shy" from age 5 months and "stranger anxiety" seemed to be excessive from age 6-12 months. We were particularly impressed by how frequently baby M. appeared "sad," tearful and irritable.

Case II. Mother : Mrs. Y. was a 28-year-old woman, hospitalized on 2 occasions prior to our present observations, diagnosed as having schizophrenia, undifferentiated type with marked depressive features. She cared for her baby girl a total of 13 months in the infant's first year and a half of life. Mrs. Y. was quite interested in her infant, nevertheless the interest was always expressed from a distance in a relatively passive manner. She usually sat at a considerable distance from the infant, tense, affectively constricted, depressed, but always keeping a watchful eye on the baby. If the baby gave some brief sign of distress, Mrs. Y.

would immediately glance over but without moving towards the infant. If the baby's distress persisted she would then go to the baby, relieve whatever distress was present and then move back to her original position of "attentive distance." She appeared to judge the physical needs of the infant appropriately be it hunger, fatigue, or a dirty diaper and she would gratify the need with a certain efficiency. Mrs. Y.'s movements in caring for her infant however were quite slow, consistent with the general motor retardation which accompanied Mrs. Y.'s depression.

Whenever she handled her baby Mrs. Y.'s face appeared tense and depressed. When Mrs. Y. engaged in social interaction with her infant her actions were quite passive. For example on the relatively few occasions Mrs. Y. played with her infant, she did not actively participate in the play. Instead, Mrs. Y. would drop a toy in the play pen and would then passively stand by and watch the baby play with it. This "passive" closeness was only of short duration. She would then re-establish her distance from the infant. When the baby was 6 months old, Mrs. Y. began to show increased signs of depression, agitation and weeping. As Mrs. Y. progressively became more depressed the physical distance she maintained between herself and her infant lessened and Mrs. Y. spent much more time rocking and holding her infant. Four months later, Mrs. Y.'s depression became very acute and she was hospitalized.

Infant: As Mrs. Y.'s symptoms of depression became more acute, Baby L. (a girl) began to frequently appear sad, lachrymose and irritable. Laughing and smiling in the infant occurred relatively infrequently. The baby showed little spontaneous pleasure in her motor activities and in her play with toys. Baby L. gradually became hypoactive and she began to show regression in her motor development as well. At age 7 months Baby L. lost the ability to sit up after she had been capable of sitting for a month.

Case III. Mother: Mrs. D. was a 27-year-old woman, hospitalized on several occasions prior to our study with a diagnosis of paranoid schizophrenia. She cared for her baby (a boy) for the first 11 months of his life. Mrs. D.'s care of her infant was characterized by the following behavior: She consistently held the infant very close to her, frequently making such comments as "he is so helpless, just like me" and "for once I feel I am needed, important." With the baby, Mrs. D. appeared tense, rigid, and depressed. Her face was "sad," inclined to tears at times; at other times, Mrs.

D. was emotionally "flat." Her movements in caring for the baby's needs, i.e., dressing and undressing the infant, were slow. She engaged the baby in play relatively infrequently, and only rarely would she actively stimulate him to laugh or smile. She would sit and gaze at him for long periods of time. She seemed to judge his physical needs appropriately, and when he was in distress she would actively and immediately investigate the cause. She held him, rocked him and comforted him frequently. Mrs. D. developed symptoms of acute psychosis when the baby was 8 months of age but she refused to be hospitalized until 4 months later. During the 4 months preceding her hospitalization Mrs. D. became increasingly depressed, agitated and tearful in her interaction with the infant though she still maintained her active attentiveness to the infant's physical needs.

Infant: From the age of 5 months onward Baby F.'s face was characterized by a somber stern expression. He was quick to cry, irritable, and frequently appeared tearful and sad. Laughing, smiling and spontaneous vocalizations were relatively infrequent. He showed little in the way of "delight" with his own movements. Playing with toys was done with interest but without the frequent spontaneous expressions of pleasure that the infants raised by the foster parents so often showed. Baby F. showed no evidence of retardation in motor development.

Case IV. Mrs. C. was a 29-year-old negro woman, the one schizophrenic mother whose infant did not show any evidence of early emotional disorder. Mrs. C. was hospitalized on one occasion prior to our study, diagnosed as having paranoid schizophrenia. She cared for her baby boy throughout his entire first 1½ years of life. She was very active with her infant, stimulated him to roll over, sit-up, walk, talk. She laughed with him, played with him and thoroughly enjoyed her activities with him. She was responsive to his physical needs and would smile, laugh and talk while handling him. With her older children she was firm and assertive. No one particular parental behavior set her apart from the foster parents we observed. Her schizophrenic illness was in remission throughout the infant's first year and a half and she was not depressed. Her infant's emotional and physical growth showed no striking deviation when contrasted with the growth of the infants reared by the foster parents.

The infants reported in cases I, II and III each developed signs of chronic depression.

The mothers of these infants were the only mothers observed who developed signs of acute psychosis while caring for their babies. This circumstance alone however did not define for us specifically what in the behavior of these mothers led to the depressive picture seen in their infants. We were particularly impressed by the following specific variables in the behavior of the 3 schizophrenic mothers which preceded and may have caused the appearance of chronic "tearfulness," "irritability," and "sadness" in their infants: 1. The primary affective state these mothers showed in the presence of their infants was constant and severe depression; 2. These mothers evidenced relatively little actively joyful or pleasurable affect in their interaction with their infants; 3. They engaged in relatively little active play with their infants. We wondered whether the presence of a depressed affect in the mother in and of itself could be a factor responsible for the depressed picture observed in their infants. It has long been known that an infant can transiently "catch" a depression from the mother. Charles Darwin(3) described this phenomenon in his own infant as follows:

when a few days over six months old his nurse pretended to cry, I saw that his face instantly assumed a melancholy expression with the corners of the mouth strongly depressed.

Many others have described this process and have labelled it "the contagion of feeling." As described, this process might represent only the infant's mimicry of the facial expression of the nurse or mother. Such workers as Eschallona(4), Burlingham(5) and Spitz(6), however, cite instances in which true feelings are stimulated in children by "contagion." While such instances have been reported, we feel that the full developmental significance of the process of contagion has not been adequately investigated. For example what would be the long-term effect on the infant of a mother who constantly exposes her growing baby to weeping over a sustained period of time? Does the infant "learn" a pattern of depression from such a mother due to the constant reinforcement of this emotional pattern in the infant by the process of "con-

tagion?" It would seem that such a constant reinforcement of a particular neural pathway of affective expression (depression) early in the life of the infant could permanently establish a depressed pattern of neural discharge. The infants described in cases I, II, and III may have developed their depressions by just this mechanism. Perhaps Anna Freud(7) had this process in mind when she recently spoke of infants who "follow" their mothers into depression. Our data do not firmly establish "contagion" as the cause of the depressions in the infants we observed. In part this is because we have not been able to exclude the importance of other variables which may have influenced the infants' emotional development. For example, "tenseness" in the mothers' handling of the infants, the absence of "play," and/or the relative lack of pleasurable responses in the mother may have been important if not the important variables responsible for the depressions in the infants. It is also possible that no one variable alone can cause early depression and that "contagion" was but one of a number of variables which together were responsible for the observed emotional maldevelopment. Our thoughts on the early "contagion of depression" led us to wonder about the "contagion of elation." A study of infants whose mothers are inappropriately elated would also be of interest. Using Anna Freud's phrase, does the infant by early contagion and learning, "follow" its mother into the inappropriate use of elation as a psychopathological defense?

The data reported in case I and our experience with a second case seen in private consultation suggested that a mother with catatonic symptoms might have a particularly harmful effect on the growing infant. In both cases, the infants observed showed signs of significant physical and emotional deterioration. It may be that catatonic withdrawal in the mother provides an environment for the infant which is equivalent to purely custodial institutional care. Spitz(8) has demonstrated the harmful effects of the latter. We plan to do a special study of infants with mothers diagnosed as having catatonic schizophrenia. Though our data to date are quite limited, we believe that the clinician involved in the outpatient

treatment of a catatonic schizophrenic mother should be particularly alert to the adverse effects such a mother might have on the growth of her infant.

The observations that 3 of the schizophrenic mothers played relatively little with their infants when compared with non-schizophrenic mothers pointed up to us how much the normal infant's life consists of his parents actively engaging him in "play." We wondered about the special importance of parent-child play during early infancy in establishing pleasurable affectionate relationships between child and parent. It also seemed that parent-infant play might be an important part of a process in which the normal child learns to enjoy the use of leisure time in later life.

The observations we have reported so far are based on following the infants discussed in cases I, II and III up to the ages of 14 months. Subsequently, their emotional and physical development was markedly influenced by: 1. The separation from the mother which occurred at the time the mother was hospitalized and 2. The many separation and deprivation experiences which followed. We were surprised at how frequently such separation and deprivation experiences occurred following the mother's initial hospitalization. The data below illustrate the number of such experiences occurring to these infants in their first 2 years of life.

Baby M. and Baby L. were each placed with foster mothers after their mothers were initially hospitalized. Both mothers were subsequently discharged from their respective hospitals. Baby M. and Baby L. were removed from their foster mothers, reunited with their mothers only to re-experience separation when their mothers were again re-hospitalized. (The fact that these mothers were involved in our study was unrelated to their apparently premature discharges.) Baby L. was then placed with 2 different foster mothers. Baby M. was placed in an institution for 3 months and then placed in a foster home. Baby F. was placed with the maternal grandmother on 3 different occasions for long periods of time. As they experienced these multiple separations from parents and substitute parents all 3 infants showed increased signs of irritability, depression and marked and persistent "stranger anxiety," minimal smiling, decreased social re-

sponses, disturbed sleep patterns, and gastrointestinal dysfunction. Subsequently we have been surprised at the resiliency shown by 2 of the infants when they were finally placed in "good" foster homes for sustained periods of time. Both of these children are now 2½ years old and each appears to be moving along the lines of healthy personality development.

The multiple separation experiences noted above may account in part for the high incidence of psychopathology reported in children of 2 schizophrenic parents. Studying only schizophrenic women mated to schizophrenic partners probably introduced several important selective factors. Schizophrenic women who choose schizophrenic mates may have more psychopathology and consequently show more disturbed parental behavior than schizophrenic women who choose non-schizophrenic partners. Also, our selection necessarily meant that the fathers were highly disturbed persons. The schizophrenic fathers in the cases studied were either absent or relatively ineffectual and in all instances were a constant source of stress to the mother. This lack of a stable father was one of the factors responsible for the frequent separation and deprivation experiences suffered by these infants subsequent to their mothers' hospitalizations.

SUMMARY

We have observed the early development of children of 2 schizophrenic parents. Three of the 4 children raised by their original schizophrenic parents developed clear-cut signs of depression and irritability in infancy. None of the 4 infants raised by foster parents developed any such clear-cut signs of emotional disorder. Our data suggest that the parental behavior of their schizophrenic mothers was at least partially responsible for the early emotional maldevelopment observed in their 3 infants. All 3 schizophrenic mothers were consistently depressed with their infants. The "contagion of depression" from mother to infant was discussed and it was suggested that this phenomenon caused an enduring depressive pattern of affective discharge in the infants we observed. It was also noted that all 3 schizophrenic mothers indulged in relatively little active play with their infants and

showed relatively little pleasurable responsiveness to their infants. Certain observations suggested to us that a mother with acute catatonic symptoms may have a particularly harmful effect on the physical and emotional growth of an infant. We were also struck by the many separation and deprivation experiences occurring to infants reared by schizophrenic mothers mated to schizophrenic partners. We are continuing our study of infants with 2 schizophrenic parents. This group offers an opportunity to explore a number of hypotheses which we shall comment on in the future.

THE ROLE CONCEPT, A BRIDGE BETWEEN PSYCHIATRY AND SOCIOLOGY

J. L. MORENO, M.D.¹

THE THIRD PSYCHIATRIC REVOLUTION

According to Zilboorg(1) two psychiatric revolutions have taken place in the last 3 centuries. Each psychiatric revolution was accompanied by a new body of theories and by new methods of clinical practice. The first psychiatric revolution(1) was connected with the name of Philippe Pinel, his freeing of inmates from chains (1792); the second psychiatric revolution(1) with Sigmund Freud, his treatment on an individual basis through psychoanalysis (1893). In retrospect, Zilboorg's view requires basic correction. The second psychiatric revolution had at least two other highlights: Ivan P. Pavlov's conditioned reflex (1904) and Adolf Meyer's psychobiology (1906).

There is wide consensus that we are now in the midst of the "third" psychiatric revolution(2, 3). Psychoanalysis faces its greatest crisis, it is in decline in the West and is rejected in the Communistic countries of the East(4). The new era is one of multiple innovations which have set the pace for new developments in psychiatry. It is characterized by the group psychiatric approach (5-8). The theories of interpersonal relations(9, 10), microsociology and sociometry and the theories of the encounter, spontaneity and creativity(11) have opened up vast areas of research in psychiatry, social psychology and social anthropology. New methods of therapy as group psychotherapy, psychodrama, sociodrama, psychosomatic medicine(12) and psychopharmacology (13) have been introduced. The ideas of the therapeutic society, therapeutic community, the day hospital and the "open door" of prisons and mental hospitals are beginning to replace the older coercive methods of the management of prisoners and mental patients.

It may be appropriate here to quote Dr. William Alanson White from an address at the Round Table on the "Application of the

Group Method to Classification"(6) held in Philadelphia, May 31, 1932.

I remember visiting, a few years ago, a prison in the East with about one thousand inmates. It had no walls and only a few cells. The dormitory system, similar to that in schools, was in use. On the first occasion I found no men in the solitary cells and on the second occasion only one. The men were free to conduct themselves and the warden was clever enough to handle the men so that they felt comfortable. They did not run away nor did they commit acts which would have made the running of the prison impossible.—Some years ago Congress made an appropriation for a prison for Washington, D. C. Roosevelt picked a committee to decide upon recommendations and plans. Among those he chose was a banker, a very well-known philanthropist. Hearing of his appointment, the man immediately protested, saying: "I cannot serve upon this committee. I know nothing about the project. I never was in a prison in my life." The President responded: "That's just why I want you." A prison was erected without walls and with no cells. It still functions successfully.

American psychiatrists traveled in recent years to Russia and England in search of "new" ideas. Had they looked carefully they would have found them in their own back yard.

A new body of theory developed in the last 30 years which aimed to establish a bridge between psychiatry and the social sciences; it tried to transcend the limitations of psychoanalysis and behaviorism by a systematic investigation of social phenomena. One of the most significant concepts in this new theoretical framework is the role concept.

THE PSYCHIATRIC ROLE CONCEPT(7)

Current surveys of the origin and development of role theory and role concept emphasize the contributions made by sociologists and psychologists but neglect the contributions of psychiatrists. The reader gets the impression that psychiatrists had

¹ Moreno Institute, Department of Research, New York, N. Y.

nothing to do with the development of role concepts. The authors of these surveys are often psychiatrists(14). Why do these authors look for the origin of the new ideas in other sciences, neglecting their own, psychiatry? Psychiatrists are often given second place when it comes to theory; they react with inferiority feelings when they are accused by psychologists and sociologists of being less scientific. Sociologists in contrast suffer frequently from a superiority bias, writing being their favorite occupation rather than observing and experimenting.

It is only fair to point out that besides non-medical authors, numerous psychiatrists(15-45) have had a profound bearing upon the development of the role concept influencing many sociological and psychological authors in their own, more academic formulations.

HISTORY OF THE TERM ROLE

Role, originally an old-French word, which penetrated into medieval French and English, is derived from the Latin "rotula." In Greece and also in ancient Rome, the parts in the theater were written on the above mentioned "rolls" and read by the prompters to the actors who tried to memorize their part by heart; this fixation of the word role appears to have been lost in the more illiterate periods of the early and middle centuries of the Dark Ages, for their public presentation of church plays by laymen. It was not until the 16th or 17th centuries, with the emergence of the modern stage, that the parts of the theatrical characters were read from "roles," paper fascicles. Whence each scenic "part" becomes a role(26).

Role is thus not a sociological concept, it came into the sociological vocabulary via the drama. It is often overlooked that modern role theory had its logical origin and its perspectives in the drama. It has a long history and tradition in the European theater from which gradually developed the therapeutic and social direction of our time. It is from Europe that the seed of these ideas were transplanted to the U.S.A. in the middle of the twenties(5). From the roles and counter roles, the role situations and role conserves developed naturally their modern extensions: role player, role play-

ing, role expectation, acting out, and finally, psychodrama and sociodrama. Independently, the sociological concept of role taking by G. H. Mead(46) took form (1934) and was further developed by R. Linton(47) (1936); both of these men were apparently unaware of the basic dependence of the process of role taking upon the drama. Many American sociologists have monopolized the concept of role, especially T. Parsons(48), as if it were sociological property. But most terms and meanings which Parsons and associates present in their writings can be found in prior publications(52).

DEFINITION OF ROLE

Role can be defined as the actual and tangible forms which the self takes(20). We thus define the role as the functioning form the individual assumes in the specific moment he reacts to a specific situation in which other persons or objects are involved. The symbolic representation of this functioning form, perceived by the individual and others, is called the role. The form is created by past experiences and the cultural patterns of the society in which the individual lives, and may be satisfied by the specific type of his productivity(23).—Every role is a fusion of private and collective elements. Every role has two sides, a private and a collective side(21).

CONSTRUCTS OF THE ROLE

The role concept cuts across the sciences of man, physiology, psychology, sociology, anthropology and binds them together on a new plane. The sociologists, G. H. Mead(46) and R. Linton(47), limited the theory of roles to a single dimension, the social. The psychodramatic role theory operating with a psychiatric orientation, is more inclusive. It carries the concept of role through all dimensions of life; it begins at birth and continues throughout the lifetime of the individual and the *socius*. It has constructed models in which the role begins to transact from birth on. We cannot start with the role process at the moment of language development but in order to be consistent we must carry it through the non-verbal phases of living. Therefore, role theory cannot be limited to social roles, it must include the 3 dimensions, social roles, expressing the social dimension, psychosomatic roles expressing the physiological dimension, and psy-

chodramatic roles expressing the psychological dimension of the self.

Illustrations of psychosomatic roles are the role of the eater and the sexual role. Characteristic patterns of interaction between mother and infant in the process of eating produce role constellations of the eater which can be followed up throughout the different life periods. Psychodramatic forms of role playing as role reversal, role identification, double and mirror playing, contribute to the mental growth of the individual. The social roles develop at a later stage and lean upon psychosomatic and psychodramatic roles as earlier forms of experience. (See Table of Role Classifications below.)

FUNCTION OF THE ROLE

"The function of the role is to enter the unconscious from the social world and bring shape and order into it" (5). The relationship of roles to the situations in which the individual operates (status) and the relation of role as significantly related to ego has been emphasized by Moreno (7).

Everybody is expected to live up to his official role in life, a teacher is to act as a teacher, a pupil as a pupil, and so forth. But the individual craves to embody far more roles than those he is allowed to act out in life, and even within the same role one or more varieties of it. Every individual is filled with different roles in which he wants to become active and that are present in him in different stages of development. It is from the active pressure which these multiple individual units exert upon the manifest official role that a

feeling of anxiety is often produced (7).

Every individual—just as he has at all times a set of friends and a set of enemies—has a range of roles in which he seems himself and faces a range of counter-roles in which he sees others around him. They are in various stages of development. The tangible aspects of what is known as "ego" are the roles in which he operates, the pattern of role-relations around an individual as their focus.—We consider roles and relationships between roles as the most significant development within any specific culture (17).

Role is the unit of culture; ego and role are in continuous interaction.

ROLE PLAYING, ROLE PERCEPTION AND ROLE ENACTMENT (19)

Role perception is cognitive and anticipates forthcoming responses. Role enactment is a skill of performance. A high degree of role perception can be accompanied by a low skill for role enactment and *vice versa*. Role playing is a function of both role perception and role enactment. Role training, in contrast to role playing is an effort, through the rehearsal of roles, to perform adequately in future situations.

ROLE PATHOLOGY (51)

Regressive behavior is not a true regression but a form of role playing. In paranoiac behavior, the repertory of roles is reduced to distorted acting in a single role. The deviate is unable to carry out a role *in situ*. He either overplays or underplays the part, inadequate perception is combined with distorted enactment. Histrionic neurosis of ac-

TABLE OF ROLE CLASSIFICATIONS *

Origin	Degree of Spontaneity	Content	Quantity	
Collective Roles	Role Taking (Conserve)	Psychosomatic Roles (<i>e.g.</i> , Role of the Eater)	Deficiency of Roles	
Individual Roles	Role Playing	Psychodramatic Roles	Adequacy of Roles	
	Role Creating	Social Roles	Superiority of Roles	
Time	Warming up Speed	Consistency	Rank	Form
Expectancy (Future)	Slow	Weak	Dominant	Flexible
Presentness	Average	Balanced	Recessive	Rigid
	Fast			
Reminiscent (Past)	Overheated	Strong

tors is due to the intervention of role fragments "alien" to the personality of the actor(7).

CO-UNCONSCIOUS STATES AND THE "INTER-PSYCHE"(18)

By means of "role reversing" one actor tries to identify with another, but reversal of roles can not take place in a vacuum. Individuals who are intimately acquainted reverse roles more easily than individuals who are separated by a wide psychological or ethnic distance. The cause for these great variations are the developments of co-conscious and co-unconscious states. Neither the concept of unconscious states (Freud) nor that of collective unconscious states (Jung) can be easily applied to these problems without stretching the meaning of the terms. The free associations of A may be a path to the unconscious states of A; the free associations of B may be a path to the unconscious states of B; but can the unconscious material of A link naturally and directly with the unconscious material of B unless they share in unconscious states? The concept of individual unconscious states becomes unsatisfactory for explaining both movements, from the present situation of A, and in reverse to the present situation of B. We must look for a concept which is so constructed that the objective indication for the existence of this two-way process does not come from a single psyche but from a still deeper reality in which the unconscious states of two or several individuals are interlocked with a system of co-unconscious states. They play a great role in the life of people who live in intimate ensembles like father and son, husband and wife, mother and daughter, siblings and twins, but also in other intimate ensembles as in work teams, combat teams in war and revolution, in concentration camps or charismatic religious groups. Marriage and family therapy, for instance, has to be so conducted that the "interpsyche" of the entire group is re-enacted so that all their tele-relations, their co-conscious and co-unconscious states are brought to life. Co-conscious and co-unconscious states are, by definition, such states which the partners have experienced and produced jointly and which can, there-
